A double-blind RCT of bifrontal and bitemporal ECT in acute mania also demonstrated the efficacy of ECT in mania (Hiremani *et al.* 2008). In addition, patients with mixed symptoms of depression and mania responded particularly well to ECT (Gruber *et al.* 2000; Medda *et al.* 2010, 2014; Valenti *et al.* 2008; Vieta 2005). Given the benefit of anticonvulsant medications in treating mania and the evidence that ECT may exert its therapeutic effect by raising the seizure threshold (Sackeim 1999), the efficacy of ECT for mania is not surprising. Catatonia secondary to mania and delirious mania represent other clinical scenarios in which ECT may offer advantages in efficacy and rapidity of response compared with pharmacotherapy (Elias *et al.* 2021; Taylor and Fink 2003).

Despite a rapid increase in studies evaluating alternative mood stabilizing medications, including newer anticonvulsants and atypical antipsychotics, there is a lack of research comparing the potential benefits of ECT in the acute and maintenance treatment of bipolar disorder (Fink 2001; Keck *et al.* 2000). This is regrettable given the advantages of ECT as a mood stabilizer that can effectively treat both the manic and the depressed phases of the illness. ECT has been given safely to children with intractable mania (Hill *et al.* 1997) and to patients with dementia and comorbid mania (McDonald and Thompson 2001). ECT also may have an important role in the treatment of mania during pregnancy, given the potential teratogenic effects of many anticonvulsant medications and the potential harm to both the mother and the fetus from a prolonged affective episode (Spodniakova *et al.* 2015).

It is unclear whether unilateral ECT is as effective as bilateral ECT in the treatment of mania. Hiremani *et al.* (2008) found both bifrontal and bitemporal ECT effective for mania with equivalent side-effect burden, although patients had a more rapid improvement with bifrontal electrode placement. Future research is needed to clarify the role of ECT in the treatment of mania, although clear evidence indicates that ECT is an effective treatment and should be included in any algorithm of therapy for treatment-resistant, severely disabling, catatonic, or delirious mania, as well as for mixed states (Jacobowski *et al.* 2013; Nivoli *et al.* 2012).

Schizophrenia

With the introduction of clozapine and the atypical antipsychotics, ECT has become a third-line treatment for schizophrenia in the United States, but ECT may be a first-line treatment for schizophrenia in some eastern hemisphere countries such as India and China (e.g., McDonald 2012). ECT continues to have an important role in the treatment of acute psychotic episodes, catatonic schizophrenia, and neuroleptic malignant syndrome (Matheson *et al.* 2010; Pompili *et al.* 2013; Tharyan and Adams 2005). The recommendations of the 2001) state that ECT is an effective treatment for schizophrenia during acute onset of symptoms, when the catatonic subtype of schizophrenia is present, and when there is a history of a positive response to ECT.

ECT is more beneficial for the treatment of positive symptoms of schizophrenia than for negative symptoms (Chanpattana and Sackeim 2010; Pawelczyk *et al.* 2014). Depressive disorders comorbid with schizophrenia may also respond favorably (Grover *et al.* 2020). ECT has also been shown to be effective in augmenting antipsychotic treatment in treatment-resistant schizophrenia (Painuly and Chakrabarti 2006; Ravanic *et al.* 2009). A Cochrane Database review (*n* = 1,285) concluded that moderate-quality evidence supported the efficacy of ECT added to standard care for medium-term clinical response among patients with treatment-resistant schizophrenia (Sinclair and Adams 2014). A randomized trial found bilateral ECT effective as an add-on to clozapine for treatment-refractory psychosis in schizophrenia, with a 50% response rate in this difficult-to-treat population (Petrides *et al.* 2015). A metaanalysis of 18 RCTs reported that the number needed to treat when adding ECT to clozapine was 4 for clinical response and 14 for remission, and the number needed to harm was 4 for subjective memory complaints (Wang *et al.* 2018). ECT may also improve symptom control when added to other antipsychotics for treatment-resistant schizophrenia, although, not surprisingly, ECT plus clozapine may be the most effective combination (Ahmed *et al.* 2017; Wang *et al.* 2015; Zheng *et al.* 2016). Maintenance ECT may help sustain this initial benefit among patients with schizophrenia on clozapine and others with schizophrenia who benefited from an initial course of ECT (Ward *et al.* 2018b; Youn *et al.* 2019).

ECT combined with neuroleptic therapy has been reported as effective in the management of aggressive behavior for patients with schizophrenia (Hirose *et al.* 2001), but analysis of seven RCTs from China showed no benefit for agitation over antipsychotic treatment in schizophrenia (Gu *et al.* 2017).

There has been research to support bifrontal (as opposed to bitemporal) electrode placement as providing better treatment response and tolerability in schizophrenia, although the data are limited (Bansod *et al.* 2018; Phutane *et al.* 2013).

As previously mentioned, catatonic schizophrenia is very responsive to ECT (Fink 2013; van Waarde *et al.* 2010). ECT can be an important treatment in cases where benzodiazepines are ineffective and patients do not respond to antipsychotics or antipsychotics are relatively contraindicated because of unclear diagnosis of catatonia versus neuroleptic malignant syndrome (Rosebush and Mazurek 2010).

Other Medical and Psychiatric Disorders

ECT can be a life-saving treatment for patients with catatonia regardless of the etiology, including catatonia resulting from a medical disease (e.g., systemic lupus erythematosus, neuroleptic malignant syndrome, *N*-methyl-D-aspartate receptor encephalitis) (Bica *et al.* 2015; Morcos *et al.* 2019; Warren *et al.* 2019). Response rates to ECT in catatonia of any origin are 80% or higher (Luchini *et al.* 2015). Patients with developmental delay complicated by catatonia, mood symptoms, or self-injurious behavior have experienced improvements in all these domains with ECT (Aziz *et al.* 2001; van Waarde *et al.* 2001; Wachtel *et al.* 2018).

A matched case-control study of over 22,000 patients with PTSD and MDD found that compared to antidepressant therapy alone, ECT combined with antidepressants was associated with a significant reduction of PTSD and MDD severity, as well as fewer completed suicides and lower cardiovascular and all-cause mortality (Ahmadi *et al.* 2016). However, RCTs for ECT treatment of PTSD are sparse and have low sample sizes.

Citing a case report of a decrease in PTSD symptoms when traumatic events were recalled immediately before each ECT session (Gahr *et al.* 2014), Andrade *et al.* (2016) hypothesized that ECT is effective because the treatment impairs reconsolidation of reactivated, emotionally aversive memories. A subsequent randomized trial failed to prove this hypothesis but did demonstrate effectiveness for PTSD comorbid with depression (Tang *et al.* 2021). Limited evidence (no RCTs) suggests that ECT may relieve symptoms associated with OCD (Fontenelle *et al.* 2015) and schizophrenia complicated by OCD (Lavin and Halligan 1996).

Case reports and retrospective reviews have demonstrated that ECT can alleviate behavioral and psychological symptoms of dementia, including associated depression, psychosis, and agitation. Such patients would be at increased risk of delirium during the acute course of ECT, but the limited existing evidence does not indicate significant worsening of the underlying dementia (Hermida *et al.* 2020, 2022; Liu *et al.* 2014; Rodriguez-Sosa *et al.* 2013; Tang *et al.* 2014; Ujkaj *et al.* 2012).

ECT may also be therapeutic for certain neurological diseases. The administration of ECT raises the seizure threshold, and ECT can interrupt status epilepticus (Pinchotti *et al.* 2018) and treat intractable seizures (Shah *et al.* 2012). ECT is effective in treating psychosis and depression in patients with Huntington's disease (Adrissi *et al.* 2019; Petit *et al.* 2016). ECT has also been demonstrated to improve motor symptoms of Parkinson's disease without worsening cognition (Faber and Trimble 1991; Kellner *et al.* 1994; Rasmussen and Abrams 1991; Takamiya *et al.* 2021). A metaanalysis of five studies reported that ECT acutely improves global motor functioning in patients with Parkinson's disease, with a notable effect size of 1.68 (Fregni *et al.* 2005). These reports have included patients with and without psychiatric illnesses; ECT improves the motor symptoms of Parkinson's disease independently of its effects on the patient's mood. Favorable predictors of response include advanced age, severe disability (on-off syndromes), and painful dyskinesias. Reduction in the symptoms of Parkinson's disease tends to occur during the first several sessions of ECT. However, the effects of ECT are not permanent and usually last from several days to several months, although prolonged improvement has been reported in a few patients. Maintenance ECT also has been shown to be effective for up to 4 years in treating the motor symptoms of Parkinson's disease (Aarsland *et al.* 1997; Wengel *et al.* 1998). As expected, ECT also improves depressive symptoms in persons with Parkinson's disease (Borisovskaya *et al.* 2016).

ECT has been reported to relieve pain symptoms associated with primary depression as well as pain among primary pain patients with secondary affective symptoms (Rasmussen and Rummans 2002), although acutely ECT may increase risk of headaches and musculoskeletal pain (Chahine *et al.* 2014). ECT may exert some analgesic effects independent of effects on mood, as evidenced in a trial with positive results using ECT to treat fibromyalgia (Usui *et al.* 2006). Similar positive results exist in case reports about ECT for refractory phantom limb pain (Rasmussen and Rummans 2000), neuropathic pain (Abdi *et al.* 2004), and complex regional pain syndromes (McDaniel 2003).

Electroconvulsive Therapy Use During Pregnancy

During pregnancy, ECT is an effective, safe treatment for women with severe manic and depressive symptoms according to a joint report by the American Psychiatric Association and the American College of Obstetricians and Gynecologists (Yonkers *et al.* 2009). As with pharmacotherapy, ethical concerns limit randomized prospective trials to assess efficacy and safety of ECT in pregnancy, although ECT has been safely used in all three trimesters of pregnancy (Rabheru 2001).

A review of 338 case reports from 1941 to 2007 identified 25 cases of fetal complications during ECT, of which less than half were deemed possibly or probably related to ECT, and 20 cases of maternal complications (90% of which were deemed possibly or probably related to ECT) (Anderson and Reti 2009). The efficacy rates among these case reports were in keeping with those of nonpregnant patients (61% for schizophrenia, 84% for depression). A more recent review likewise indicated a good safety profile for ECT during pregnancy. Risks for the mother were deemed comparable to those for nonpregnant patients, except for infrequent premature contractions and preterm labor. Reviewers reported a lack of evidence that ECT increases risk for miscarriages or congenital anomalies (Ward *et al.* 2018a). Not all reviews have reached the same conclusions, however. One review reported additional and more frequent adverse events with ECT during pregnancy, probably because there was no attempt at causal attribution (i.e., due to ECT vs. other causes) for adverse events, unlike in other reviews (Coshal *et al.* 2019).

The risks of administering ECT during pregnancy have been reviewed by Rabheru (2001). Possible strategies to mitigate these risks include obstetrics consultations and performance of the procedure in facilities equipped to deal with obstetric emergencies. Physiological problems in pregnancy that could affect ECT risks include delayed gastric emptying, aortocaval compression causing placental insufficiency, uterine restriction on respiratory ventilation when supine, and seizure-induced elevations in oxytocin and subsequent premature uterine contractions. Use of antacids, adequate hydration, elevation of the right hip, fetal heart rate monitoring, and availability of tocolytic therapy if needed are strategies to address these respective pregnancy-specific issues in ECT administration (Saatcioglu and Tomruk 2011; Ward *et al.* 2018a). The risks of ECT in pregnancy must be considered in context; there are also potential risks for the mother and fetus with untreated mental illness as well as with use of psychotropic medications, some of which have known teratogenic effects (Ward *et al.* 2018a).

FDA Final Order on Reclassifying Electroconvulsive Therapy Devices

On December 26, 2018, the FDA issued a final order or regulatory document on the reclassification of devices for the administration of ECT (U.S. Food and Drug Administration 2018). This document provides regulatory guidance on how device manufacturers can market their products in the United States. The FDA recategorized ECT devices from Class III to a less restrictive class, Class II, when marketed "for the treatment of catatonia or a severe MDE associated with MDD or bipolar disorder in patients age 13 years and older who are treatment-resistant or who require a rapid response due to the severity of their psychiatric or medical condition." However, the FDA left several diagnostic categories in Class III that are commonly treated with ECT, including schizophrenia and mania. This was despite the efforts by the American Psychiatric Association and other groups to argue for a less restrictive classification for many of these psychiatric diagnoses (Binder and Levin 2016).

A Class II category permits manufacturers to sell devices for these diagnoses provided they include "special controls" in the labeling, which include pre-ECT medical and psychiatric assessment, patient monitoring during the procedure, use of general anesthesia and neuromuscular blocking agents, mouth and dental protection during the procedure, electroencephalogram (EEG) monitoring during an ECT-induced seizure to the point of seizure termination, adequate skin preparation and use of conductive gel for stimulus electrode placement, and cognitive status monitoring of the patient before and during ECT. They also include the importance of clinical training for practitioners and patient information in the form of brochures, leaflets, or videotapes to inform patients and their families about the relevant risks and side effects of ECT.

What are the clinical implications of the final order? The final order specifies that the "FDA is not permitted to limit or interfere with the authority of a health care professional to administer any legally marketed device to a patient for any condition or disease within a legitimate clinician-patient relationship" and that "FDA does not regulate off-label use of ECT by physicians." The off-label use of ECT is similar to the off-label use of medications. The physician should document both the risks and benefits of the procedure compared to other treatment options and should document the consent process. As was discussed in the previous section, ECT has been used for indications with research evidence for efficacy that were not necessarily part of the FDA indications for ECT, including neuroleptic malignant syndrome, self-injurious behavior in autism, agitated dementia, and PTSD. These indications would also be considered "off label."

For further information on the final order and relevance to clinical practice, see the resource document on the FDA final order to reclassify ECT devices prepared by an

American Psychiatric Association work group (Binder and Levin 2016) and other commentaries (Kellner *et al.* 2019; McDonald *et al.* 2016).

Administration of Electroconvulsive Therapy

Stimulus Dosing in Electroconvulsive Therapy for the Treatment of Depression

Questions about the proper management of the electrical stimulus have been central to the science and practice of ECT. Cerletti and Bini modeled ECT on the success of pharmacologically induced convulsive therapy and assumed that the stimulus should be convulsive. Interestingly, the first ECT session in 1938 involved two subconvulsive stimulations before Cerletti and Bini increased the stimulus intensity to produce a convulsion (Endler 1988). Therefore, this first session was a "titrated" ECT session with serial applications of increasing stimulus intensities passing from the subconvulsive range through the convulsive threshold. Issues in stimulus dosing that have been considered since that time include the following:

- Whether the stimulus should be subconvulsive or convulsive
- What the optimal stimulus waveform is
- If a convulsive stimulus is desired, to what degree the stimulus intensity should be in excess of the convulsive threshold
- Which physiological parameters, if any, provide useful feedback to continuously refine stimulus dosing throughout the ECT course

Convulsive, Subconvulsive, and Sham Stimulation

The use of nonconvulsive electrical stimulation to treat psychiatric disorders preceded the introduction of ECT by decades. Most of the treatments involved administering static electricity to parts of the body, including the head (Grover 1924). The availability of commercial ECT devices did not lead to the immediate replacement of subconvulsive stimulation with convulsive stimulation. Instead, some practitioners used the devices to deliver lengthy (several minutes long) subconvulsive cranial stimulation. However, it became clear that subconvulsive stimulation was associated with a poorer outcome than conventional psychotherapy in patients on the depressive/anxious spectrum, and the practice of treating patients with subconvulsive stimuli decreased (Hargrove *et al.* 1953). The elements of modified ECT (including muscle relaxation and general anesthesia) were described early in the history of ECT. The wide-scale adoption of these modifications raised new questions as to whether seizure is central to the antidepressant efficacy of ECT or whether anesthesia alone would be just as effective. The Northwick Park trial (Johnstone *et al.* 1980) and the Leicestershire trial (Brandon *et al.* 1984) are two examples of "sham" ECT studies in which anesthesia alone was compared with real ECT. It was convincingly demonstrated that real ECT is more efficacious, especially for the most severe forms of depression (Brandon *et al.* 1984; Johnstone *et al.* 1980). The efficacy of ECT was clearly linked to the production of a seizure. Neither the use of anesthesia alone without the electrical

stimulus nor the use of subconvulsive electrical stimuli appears to have real benefit in the treatment of depression.

Stimulus Waveform

Given that a convulsive stimulus is necessary for the antidepressant effects of ECT, a nearly infinite number of variations are available for formulating the stimulus waveform. The earliest ECT devices delivered a sinusoidal stimulus. Other waveforms available on early ECT devices included the "chopped" sine wave, the unidirectional pulse square wave, and the alternating brief-pulse square wave. Although some investigators suspected that sine wave stimuli might produce slightly better antidepressant effects than did brief-pulse stimuli, that suspicion was mitigated by a randomized study showing that sine wave ECT produced more memory side effects than brief-pulse ECT, irrespective of the placement of the stimulating electrode (Weiner *et al.* 1986b).

This finding of greater cognitive side effects with sine wave ECT was replicated in an efficacy study with a prospective cohort design, which showed that compared with brief-pulse stimulation, sine wave stimulation was associated with a slowing of reaction time that persisted for at least 6 months after ECT (Sackeim *et al.* 2007). The more severe cognitive side effects produced by sinusoidal stimuli may be explained by the slower rise time for each sine wave cycle as compared with the brief-pulse cycle. Consequent to the slower rise time, much of the sine wave stimulus is subconvulsive and thus presumably adds nothing to the therapeutic effect of ECT, adding only to cognitive side effects. The steep rise in the brief-pulse waveform allows the entire stimulus to be above the convulsive threshold (suprathreshold). Because much of the sine wave stimulus is nonproductive, being in the subconvulsive range, it was predicted that brief-pulse stimuli would be more efficient, requiring a stimulus of smaller magnitude to produce a seizure. Standard brief-pulse stimuli are defined by a pulse duration of 1-2 milliseconds, and ultrabrief-pulse stimuli are defined by a pulse duration of < 0.50 milliseconds. In 1980, Weiner showed that standard brief-pulse stimuli could provoke a seizure with only one-third of the energy required with sine wave stimuli (Weiner 1980). Standard brief-pulse ECT devices have currently replaced sine wave devices in the United States (Farah and McCall 1993).

Devices using ultrabrief-pulse stimuli have the advantage of increasing the efficiency of seizure induction. Abrams (2002) estimated that it takes only about 0.25 milliseconds to initiate neuronal depolarization, and wider pulse widths are inefficient and waste electrical charge. The total energy output of these ultrabrief-pulse modalities is the same as the total energy output of the standard brief-pulse widths; thus, as the stimulus pulse widths are shortened, the stimulus trains are lengthened. Ultrabrief pulse widths may have an advantage because shorter pulse widths and longer pulse trains have been shown to elicit seizures with a smaller electrical charge and therefore may have fewer cognitive side effects (Sackeim *et al.* 2008). Even in older patients with MDD, ultrabrief pulses induce seizures 84% of the time with stimuli of only 5% of the maximal ECT device output in the United States (Kellner *et al.* 2016b). This is remarkable and relevant because older patients have high seizure thresholds.

Several recent studies have assessed the efficacy and side-effect profile of brief-versus ultrabrief-pulse-width right-unilateral (RUL) ECT in MDD. In a prospective study comparing ultrabrief-pulse RUL ECT (0.3 millisecond; *n* = 74) versus brief-pulse RUL ECT (1.0 millisecond; *n* = 22) in depressed individuals, Loo *et al.* (2008) found similar depression response rates in the two groups (but a slower rate of response in the ultrabrief-pulse RUL ECT group), with better cognitive outcomes in the ultrabrief group. In a prospective randomized trial of high-dose RUL ECT in 87 depressed inpatients, Spaans *et al.* (2013a) found that patients undergoing ultrabrief-pulse ECT were significantly less likely to achieve remission--and needed significantly more treatments to do so--compared with patients receiving brief-pulse ECT. A retrospective study of 150 subjects pooled from three research samples found that fewer treatments were needed with brief-pulse than with ultrabrief-pulse RUL ECT and that remission rates were significantly higher with brief-pulse ECT (Loo *et al.* 2003). Generally, researchers have found that ultrabrief-pulse RUL ECT produced fewer neurocognitive effects (specifically on autobiographical memory) compared with brief-pulse treatment (Mayur *et al.* 2013; Verwijk *et al.* 2012) or that side effects for the two types were similar (Spaans *et al.* 2013b). Recently, Kellner *et al.* (2016b) showed that ultrabrief-pulse RUL ECT produces remission from MDD in 61.7% of depressed older adults. The same group also showed that continuation therapy with ultrabrief-pulse RUL ECT and psychotropics is more effective than psychotropics alone in maintaining remission in MDD (Kellner *et al.* 2016b). Very preliminary evidence suggests that ultrabrief-pulse RUL ECT may be effective in treatment-resistant mania (Elias *et al.* 2019; Wong *et al.* 2019).

The data on pulse width and bilateral ECT are also evolving. In a retrospective study of bilateral ECT in which 65 patients with MDD received a pulse width of either 0.5 millisecond (brief) or 0.25 millisecond (ultrabrief), the two groups had similar response and remission rates (Niemantsverdriet *et al.* 2011). In a prospective randomized trial in which 64 patients received treatment with a course of either bifrontal ultrabrief-pulse (0.3 millisecond) ECT at 1.5 times the seizure threshold or RUL ultrabrief-pulse ECT at 6 times the seizure threshold, the two patient groups showed equivalent response rates, with no changes in cognition in either group (Sienaert *et al.* 2010).

However, a randomized trial of 90 depressed patients who were treated with either RUL ECT at 6 times the seizure threshold or bilateral ECT at 2.5 times the seizure threshold, using either a traditional brief pulse (1.5 milliseconds) or an ultrabrief pulse (0.3 millisecond), found that the remission rate with ultrabrief-pulse bilateral ECT was significantly lower than that with brief-pulse bilateral ECT (35% vs. 65%). Ultrabrief-and brief-pulse RUL ECT (remission rates of 73% and 59%, respectively) were as effective as brief-pulse bilateral ECT (65%) but produced fewer cognitive side effects. Of the four treatment groups, ultrabrief-pulse RUL ECT was associated with the fewest cognitive side effects (Sackeim *et al.* 2008).

A systematic review concluded that brief-pulse-width RUL ECT was "slightly" more efficacious in treating depression and required fewer treatment sessions but was also associated with more cognitive side effects (Tor *et al.* 2015). Other groups have reviewed the data and argued against the use of ultrabrief RUL ECT, saying the evidence does not support its use as a first-line treatment when compared to brief-pulse RUL (Spaans *et al.* 2013b) or brief-pulse bilateral ECT at 2.5 times the initial seizure threshold (McCormick *et al.* 2009) as the first-line treatment. Clinicians considering the use of brief-pulse RUL versus ultrabrief-pulse RUL ECT versus bilateral ECT should take into account clinical factors such as baseline cognitive or neurological status and the severity of psychiatric symptoms, as well as practical issues such as the potential for increased length of the treatment course with ultrabrief-pulse treatments (Galletly *et al.* 2012, 2014).

The picture with ultrabrief bilateral ECT is less clear, and further research may be needed to determine the efficacy of ultrabrief compared to standard brief-pulse bilateral ECT. Some have argued that brief-pulse RUL should be used when a faster response is needed and brief-pulse bilateral

ECT should be used until the research data support the efficacy of ultrabrief bilateral ECT (Loo *et al.* 2012b).

Magnitude of the Stimulus Dose

The consensus regarding the need for convulsive (as opposed to subconvulsive) stimuli and brief-pulse waveforms would seem to make stimulus dosing in ECT a straightforward process, except for the question of the degree to which the stimulus should exceed the convulsive threshold. For years, ECT practitioners were satisfied that the answer to this question was found in the work of Ottosson (1962), who compared routine ECT with ECT modified by pretreatment with intravenous lidocaine. He found that seizures induced by lidocaine-modified ECT were shorter than those induced by routine ECT and observed an inverse relationship between seizure duration and antidepressant effect. From this work, it was widely accepted that stimulus doses producing seizures lasting at least 25 seconds have an antidepressant effect (American Psychiatric Association Task Force on Electroconvulsive Therapy 1978).

Initially, ECT was administered with bilateral (typically bitemporal) electrode placement. In 1949, Goldman introduced RUL ECT and placed stimulating electrodes over the right hemisphere rather than the mesial temporal lobes to decrease the direct stimulation of language areas and decrease cognitive side effects (Goldman 1949). Although RUL ECT was associated with fewer cognitive side effects, most studies showed that bilateral ECT had a marked therapeutic advantage over unilateral ECT for depression (d'Elia and Raotma 1975).

The clinical wisdom that bilateral ECT was more effective than RUL ECT in treating depression came into question with the work of Sackeim's research group. Sackeim *et al.* (1993) reported that when the magnitude of the electrical stimulus was just barely above the convulsive threshold, ECT with RUL electrode placement was not efficacious, despite the production of electrographic seizures typically in excess of 25 seconds. However, as the electrical dose was progressively increased, response rates in RUL ECT improved significantly and approached those of bilateral ECT. In contrast, bilateral ECT was fully efficacious with stimuli minimally above or 2.5

times the seizure threshold, but excess memory side effects accrued at the higher stimulus dose.

There is a dose-response relationship in RUL ECT only to the extent that the stimulus dose exceeds the convulsive threshold for a given patient; the absolute magnitude of the stimulus dose has no independent influence on this relationship. The efficacy of RUL ECT follows a nearly linear relationship to the degree that the stimulus dose exceeds the seizure threshold, at least through 12 times the seizure threshold (McCall *et al.* 2000). This relationship is analogous to the pharmacological treatment of depression with tricyclic antidepressants: serum blood levels are more important than the absolute oral dose in determining both efficacy and side effects.

These findings led to the following conclusions:

- With standard brief-pulse stimulation delivered with RUL electrode placement, the stimulus should be substantially above the convulsive threshold in order to ensure the effectiveness of ECT.
- With standard brief-pulse stimulation delivered with bilateral electrode placement, the stimulus should not be excessively above the convulsive threshold, in order to avoid undue cognitive side effects.

The convulsive threshold varies by a factor of at least 40 in large patient samples; thus, the mean threshold for a group of patients may not inform the threshold for an individual (Sackeim *et al.* 1991). It is clear that the convulsive threshold is related to age, sex, race, choice of stimulating electrode placement, and, perhaps, cranial dimensions (Chung 2006; Colenda and McCall 1996; Sackeim *et al.* 1991) and even volume of cerebrospinal fluid estimated on MRI (van Waarde *et al.* 2013). Still, these factors predict only a small amount of the variance in the convulsive threshold, and statistical models to predict the convulsive threshold, including age-based dosing approaches, may not yield an accurate estimate of the threshold (Colenda and McCall 1996; Tiller and Ingram 2006). In addition, a primary factor for an individual patient may be medications that affect the seizure threshold (e.g., benzodiazepines, anticonvulsants), which are difficult to account for in any algorithm estimating the seizure threshold.

Seizure Morphology

The report of Sackeim *et al.* (1993) that threshold RUL ECT produced seizures of 25 seconds or longer without antidepressant efficacy cast doubt on the clinical wisdom that the stimulus dose was therapeutic if the electrographic seizure lasted at least 25 seconds. Investigators have sought a physiological marker of treatment adequacy to replace seizure duration. The most promising candidate is seizure morphology. Ottosson (1962) reported that lidocaine changed the shape of ECT seizures and affected their duration, although the first finding is largely overlooked. Lidocaine-modified seizures, in addition to being less efficacious than standard ECT seizures, were characterized by loss of spike activity and poor postictal suppression.

Seizure morphology varies according to ECT technique. That is, greater seizure intensity correlates with ECT techniques that progress from lower efficacy (with RUL electrode placement and low stimulus intensity) to higher efficacy (with bilateral placement and high stimulus intensity) (Krystal *et al.* 1993). Electrode placement and stimulus intensity have independent and additive effects on seizure morphology. Seizures of greater intensity are characterized by higher peak ictal amplitudes, greater stereotypy of the ictal discharge, greater symmetry and coherence between the left and the right cerebral hemispheres, and more profound postictal suppression. The natural extension of this reasoning leads to the hope that seizure morphology could guide decisions about stimulus intensity as the course of ECT progresses. For example, if seizure intensity is low in the middle of the treatment course, then the treatment technique should be changed (by switching electrode placement or increasing the stimulus intensity) in order to optimize the clinical outcome. Manufacturers of ECT devices now incorporate automated measures of seizure intensity into the ECT chart recorder, and the accompanying owner's manual instructs the practitioner to increase the stimulus intensity if the seizure morphology appears to be degraded. The unstated implication is that degraded seizure morphology is a problem and that increasing the stimulus intensity will fix the problem. This instruction might have merit if stimulus intensity were the primary determinant of seizure morphology, but other factors, such as age, baseline convulsive threshold, and other intrinsic patient characteristics, probably play an equal role in determining seizure expression (McCall *et al.* 1996, 1998). For example, greater seizure durations coupled with greater seizure regularity, as shown by electroencephalography at the second ECT session, are predictive of a better antidepressant outcome at the conclusion of the ECT course, and this relation is independent of the choice of stimulus electrode placement (Kimball *et al.* 2009).

Seizure morphology is little influenced by increasing the stimulus intensity above 2.5 times the seizure threshold. Therefore, it is premature to recommend stimulus dosing based on seizure morphology. The importance of seizure morphology in predicting clinical outcome is not well understood, and more work is needed if seizure morphology is to become a practical tool for governing ECT technique. Peak heart rate has been proposed as an alternative physiological measure of treatment adequacy, with higher heart rates perhaps indicating better clinical outcomes (Swartz 2000). Again, this approach has yet to be widely accepted.

Integrating the Science of Stimulus Dosing With the Choice of Electrode Placement

Estimating the convulsive threshold. The recent advances in knowledge pertaining to stimulus dosing led to the conclusion that standard brief-pulse RUL ECT should be initiated with a stimulus known to be at least five times the seizure threshold, whereas standard brief-pulse bilateral ECT should be initiated with a stimulus about 50% above the seizure threshold. Choosing between these two strategies requires consideration of both efficacy and side effects. However, ultrabrief RUL ECT should be considered when patients are at risk for cognitive complications from ECT (e.g., Parkinson's disease).

McCall *et al.* (2000) conducted a randomized comparison of low-dose (1.5 times the seizure threshold) bilateral ECT (*n* = 37) and high-dose (8 times the seizure threshold) RUL ECT (*n* = 40). Again, depression remission rates were not significantly different with RUL electrode placement (60%) versus bilateral placement (73%), and memory effects were likewise similar. This study can be criticized for having insufficient power to detect small but meaningful effects. However, that concern was addressed in a subsequent study (Sackeim *et al.* 2009) involving 319 patients randomly assigned to receive either standard brief-pulse RUL ECT administered at 6 times the seizure threshold or bilateral ECT administered at 1.5 times the seizure threshold. Although differences between the electrode placements' antidepressant effects were again indistinguishable, the extent of autobiographical memory loss was greater in the bilateral group.

Kellner *et al.* (2010) conducted a multicenter double-blind, controlled trial in which 230 patients with MDD were randomly assigned to one of three electrode placements: bifrontal at 1.5 times seizure threshold, bitemporal at 1.5 times the seizure threshold, and RUL at 6 times the seizure threshold. They found that all three electrode placements were statistically equivalent, with remission rates of 55% with RUL, 61% with bifrontal, and 64% with bitemporal electrode placements. Notably, the patients treated with bitemporal electrode placement had more improvement in depression early in the course of treatment. In this study, the investigators used a very complete neuropsychological battery including measures of autobiographical memory and found few differences between the electrode placements on a variety of neuropsychological instruments.

The bulk of the evidence thus suggests that it is desirable to set the stimulus dose as a proportion of the convulsive threshold. The convulsive threshold of each patient should be identified, preferably by measuring convulsive threshold early in the ECT course. The most accurate means of measuring the convulsive threshold for a given patient is empirical observation through use of stimulus "titration" at the initial treatment session, a technique in which an intentionally subconvulsive stimuli is first administered, followed by administration of successively larger stimuli until a seizure is produced. This approach applies to both RUL and bilateral electrode placement.

If ECT practitioners agree with the above reasoning and use this stimulus dosing technique, they should ascertain the convulsive threshold at the first ECT session. However, some ECT researchers have argued against titration of stimulus doses with unilateral ECT and instead have encouraged practitioners to use fixed high doses of unilateral ECT (Abrams 2002) or fixed moderate doses of bilateral ECT (Kellner 2001). Concerns about stimulus dose titration include the risk that the subconvulsive stimulation inherent in stimulus titration might be medically dangerous, the subconvulsive stimulation might add to the memory side effects, or the production of a barely suprathreshold seizure with RUL placement could constitute ineffective treatment, thus rendering the first treatment a wasted effort.

Subconvulsive stimulation transiently slows the heart rate, and if a subconvulsive stimulation is administered to patients who have received a b-blocker and no anticholinergic drug, substantial asystole is a risk (McCall *et al.* 1994). However, atropine pretreatment eliminates this risk. The possibility of excess acute cognitive side effects with subconvulsive stimuli has been examined and discounted (Prudic *et al.* 1994). However, the possibility of a sluggish antidepressant response when RUL stimulus doses are titrated to a level moderately above the seizure threshold is a reasonable concern that must be weighed against the benefits associated with assessing the seizure threshold to determine the most therapeutic dose for ECT. Of course, an initial titrated suprathreshold bilateral stimulus would be closer to the therapeutic dose (or 1.5-2.5 times the seizure threshold), and the cognitive benefits of ensuring that the dose is not suprathreshold (i.e., > 3 times the seizure threshold) are more straightforward.

Alternatives to estimating the convulsive threshold. Abrams (2002) suggested that the most efficient method of administering RUL ECT is to use 100% of the maximum device capacity and a pulse width of 0.25-0.50 milliseconds and recommended changing to bilateral ECT if the patient does not improve sufficiently. This strategy takes advantage of the cognitive sparing of lower pulse widths and the efficacy of RUL ECT at high doses. The disadvantages of this strategy are the fact that it is not adjusted to the patient's seizure threshold and the potential for more cognitive side effects without therapeutic benefit.

Alternatively, twice-weekly bilateral ECT could be initiated using the half-age method (Abrams 2002). In the half-age method, the age of the patient is divided by 2; the resulting number is the percentage of the device's maximal output with which the patient is first treated (e.g., a 50-year-old would be treated at 25% of the machine's maximal output). The half-age method has been shown to be a reasonable estimate of therapeutic stimulation for patients undergoing bitemporal ECT (Petrides *et al.* 2009). As stated above, characteristics other than age that can influence a patient's seizure threshold include multiple medications (e.g., benzodiazepines, valproic acid) that the patient may be taking and anesthetic medications such as propofol. For these reasons, this calculation may be problematic.

Choosing an Electrode Placement and Stimulus Dose

Patients with the most serious complications of MDD or mania (i.e., active suicidal behavior with intent, catatonia, psychosis) should be considered for brief-pulse bitemporal ECT at 1.5-2.5 times the stimulus threshold. Consideration of high-dose (5-6 times the seizure threshold) brief-pulse (or ultrabrief-pulse) RUL ECT is appropriate given concerns about a patient's vulnerability to the cognitive side effects of ECT. No clear guidelines are available for use of RUL ECT in schizophrenia or mania, although some evidence supports bifrontal over bitemporal ECT in schizophrenia (Phutane *et al.* 2013) and acute mania (Hiremani *et al.* 2008).

Other situations favoring the use of titrated ultrabrief-pulse or brief-pulse RUL ECT (with its potential cognition-sparing effects) include treatment of depressed patients with comorbid dementia or other neurological conditions (e.g., Parkinson's disease). The treatment for these patients should minimize even transient memory side effects and may include starting at a very conservative unilateral dose (i.e., five times the seizure threshold) and increasing the dose as tolerated.

The length of a course of ECT is highly variable and may depend on the diagnostic problem that requires treatment. Courses of ECT for depression typically run for 6-10 sessions, and courses of ECT for schizophrenia may be much longer. The course length should be individualized, based on clinical response. Depressed patients rarely show major improvement after one or two sessions, only to rapidly relapse if the treatment course is terminated. At the other extreme, there is the risk of premature discontinuation of the treatment course if the patient has not achieved remission within an "average" number of sessions. If the ECT provider is considering a longer course of ECT because of failure to remit, there is a temptation to assume that the treatment technique during the additional, extended sessions should be changed to improve the chances for success (e.g., switching a depressed patient who has not remitted after eight RUL sessions to bilateral ECT). This practice has been challenged by recent evidence showing that switching to bilateral electrode placement for an extended course of ECT is highly likely to lead to remission regardless of whether the electrode placement in the first part of treatment was RUL or bilateral (Sackeim *et al.* 2020). This finding raises the possibility that it is not the switch in electrode placement that effected the remission but rather the additional treatments. This matter is not trivial as a midcourse switch to bilateral placement is associated with more severe autobiographical memory problems. The field would be helped by a clinical trial that compared switching to bilateral versus staying with RUL in depressed patients who require an extended course of ECT.

Electroconvulsive Therapy Treatment Procedure

Pretreatment Medical Evaluation

Although no medical condition is an absolute contraindication for ECT, several clinical conditions may increase the risk of complications from ECT (Tess and Smetana 2009):

- Recent myocardial infarction or unstable cardiac conditions

- Implanted cardiac devices
- Atrial fibrillation
- Any illness that increases intracranial pressure (e.g., brain tumor)
- Recent cerebral infarction, particularly hemorrhagic infarction
- Obstructive pulmonary disease or asthma
- Aneurysm or vascular malformation
- American Society of Anesthesiology physical status classification level 4 or 5

When treating high-risk patients with ECT, clinicians must evaluate the effects of ECT on cerebral and cardiac physiology and review data from the extant ECT literature to help develop individual risk-benefit ratios (American Psychiatric Association Task Force on Electroconvulsive Therapy 2001; Saito 2005; Sundsted *et al.* 2014). All patients should undergo a thorough medical and neuropsychiatric review before beginning ECT. Emphasis should be placed on diseases affecting the CNS and the cardiovascular system. The pre-ECT evaluation should include a physical examination, detailed neurological examination, mental status examination, medical history, and review of systems. The patient's mental status should be evaluated before initiation of ECT and monitored closely before administration of ECT at every session thereafter.

ECT Administration

ECT sessions usually are scheduled for the morning. The patient's bladder should be emptied before treatment. Patients should not eat or drink for at least 8 hours before receiving the treatment. Famotidine or ranitidine is given the night before and the morning of ECT to neutralize the patient's gastric contents. Alternatively, sodium citrate can be given the morning of the treatment and will have an effect within 5-10 minutes.

The patient should be instructed to limit the number of medications, and the water needed to swallow the medications, on the morning of ECT to cardiac medications (except lidocaine, which is an anticonvulsant), pulmonary medications (except theophylline, which has been associated with status epilepticus after an ECT treatment), and glaucoma medications (except cholinesterase inhibitors, e.g., echothiophate). Given that the patient's oral intake is restricted, clinicians should also consider withholding any diuretics until after the treatment, depending on the patient's cardiac status. In diabetic patients, hypoglycemic medications are usually withheld on the morning of treatment to minimize the risk of hypoglycemia in a patient who is taking nothing by mouth. The patient's blood sugar level should be checked before ECT, and hyperglycemia or hypoglycemia should be treated appropriately. An ECT treatment will result in a modest short-term increase in the patient's blood sugar. In general, patients with epilepsy or mania should continue taking their anticonvulsants during ECT. If difficulty arises in eliciting seizures, decreasing the dose of the anticonvulsant can be considered.

The standard anesthetic agent in the United States is methohexital, a short-acting barbiturate with limited anticonvulsant effects. Methohexital is given in a dose of approximately 0.75-1.0 mg/kg. An alternative anesthetic is propofol (0.75-1.50 mg/kg), which is associated with shorter seizures than methohexital and an increase in the number of missed seizures (i.e., delivery of an electrical stimulus without induction of a seizure) (Swaim *et al.* 2006). However, seizure duration has not been correlated with clinical efficacy (Sackeim *et al.* 1991), and trials comparing the use of methohexital versus propofol have not shown significant differences in the antidepressant efficacy of ECT (Avramov *et al.* 1995; Rasmussen 2014). Propofol is associated with improved hemodynamic stability and equivalent improvement in depressive symptoms in studies comparing the two anesthetic agents (Geretsegger *et al.* 2007) and has advantages in improved hemodynamics and a quicker postanesthesia recovery time (Rasmussen 2014).

Immediately after the patient is anesthetized, a muscle relaxant is administered intravenously. Succinylcholine, at doses of 0.75-1.50 mg/kg, is a widely used depolarizing blocking agent. In patients with a pseudocholinesterase deficiency, catatonia (which can lead to cardiac complications due to immobility and hyperkalemia with succinylcholine [Zisselman and Jaffe 2010]) or a musculoskeletal disease, a nondepolarizing agent such as rocuronium can be considered. The combination of rocuronium and sugammadex has been shown to reduce myalgia and headache after ECT (Saricicek *et al.* 2014).

Anticholinergic agents, such as atropine or glycopyrrolate, are used to prevent ECT-induced bradycardia and to minimize airway secretions. Glycopyrrolate does not cross the blood-brain barrier and therefore may be associated with less postictal confusion than atropine in older individuals. When a b-blocker is added to control the ECT-induced rise in blood pressure and heart rate, an anticholinergic agent should be considered since the initial response to the ECT stimulus is bradycardia. Atropine (0.4-1.0 mg) or glycopyrrolate (0.2-0.4 mg) can be given either intramuscularly 30 minutes before the ECT treatment or intravenously at the time of treatment.

Regarding dosing of the electrical stimulus, the titration or method-of-limits approach uses a table with incremental increases in the electrical energy to determine the minimal amount of energy necessary to produce a seizure (the seizure threshold) as monitored by electroencephalography. Typically, a seizure lasting 30-90 seconds occurs during treatment.

Seizures lasting longer than 3 minutes should be terminated by administering an anticonvulsant (e.g., a second dose of methohexital or propofol, or a short-acting benzodiazepine such as midazolam). Patients usually are alert and oriented 20-45 minutes after receiving an ECT treatment.

Strategies for Addressing Shortened, Missed, or Abortive Seizures

Seizure quality and duration can decrease during the course of ECT because ECT-induced seizures have anticonvulsant properties. As discussed above, seizure length is not related to clinical outcome. But there are several strategies to consider if a patient is not improving clinically and has short or poorly formed seizures. These strategies include hyperventilation, changing anesthetic agents or lowering the anesthetic agent and supplementing with short-acting opiates, increasing the spacing between electrodes to decrease shunting, increasing the patient's hydration, adding flumazenil for patients on benzodiazepines, and increasing the stimulus dose (Weiner and Reti 2017). Anticonvulsant medications (i.e., benzodiazepines, carbamazepine, valproic acid, lamotrigine) can also be held the night before an ECT treatment. Flumazenil (0.4-1.0 mg), a benzodiazepine antagonist, has been used to block the anticonvulsant

effects of benzodiazepines, although it has not been shown to increase the efficacy or seizure duration of an ECT treatment (Krystal *et al.* 1998).

Changing to the anesthetic etomidate (0.15-0.3 mg/kg) from methohexital or propofol is associated with significantly longer seizures (Stadtland *et al.* 2002), which does not appear to be dose dependent (van Lammeren *et al.* 2013). In one retrospective naturalistic study, etomidate was associated with a significantly shorter treatment course (Swaim *et al.* 2006).

Another approach to address shortened or abortive seizures is to supplement methohexital or propofol with an ultra-short-acting narcotic such as remifentanil or alfentanil and to decrease the dose of the methohexital or propofol. These opiates are potentially proconvulsant and suppress the hemodynamic response to the seizure and can provide anesthesia that will allow lower doses of methohexital or propofol (Locala *et al.* 2005; Vishne *et al.* 2005).

Ketamine (1-2 mg/kg), which has a minimal effect on the seizure threshold (Hoyer *et al.* 2014; Wang *et al.* 2012), can also be used as the anesthetic agent or as an adjunctive anesthetic agent, with the caveat that ketamine can prolong recovery and may exacerbate psychosis. However, data on the use of ketamine in ECT are still preliminary (Galvez *et al.* 2017). There is limited evidence that the use of ketamine as an anesthetic agent can augment the antidepressant response of ECT (Anderson *et al.* 2017; Loo *et al.* 2012a).

Caffeine sodium benzoate (usual dose, 120-140 mg) may be administered intravenously during ECT to maintain adequate seizure duration (Coffey *et al.* 1990). Caffeine lengthens the seizure duration during ECT without lowering the seizure threshold (McCall *et al.* 1993). At present, it is not known whether caffeine augments the antidepressant effects of ECT or increases the speed of response to ECT. Theoretically, caffeine would have little therapeutic effect on unilateral ECT, because the length of the seizure is less important than the degree to which the seizure stimulus exceeds the seizure threshold.

Management of Electroconvulsive Therapy-Related Side Effects

Headaches, Muscle Soreness, and Nausea

Headaches are a common side effect of ECT, occurring in about 5%-7% of patients (Sato *et al.* 2013), and in most cases are mild. However, they can be throbbing, usually over the forehead, and be accompanied by nausea and vomiting. Patients who experience frequent post-ECT headaches may benefit from prophylactic treatment such as aspirin, acetaminophen, or nonsteroidal anti-inflammatory drugs (e.g., intravenous ketorolac) given before the ECT treatment. For patients with a history of migraines, pretreatment with subcutaneous or intranasal sumatriptan or another migraine medication should be considered.

Muscle soreness is common after the first treatment because of intense fasciculations following administration of a depolarizing muscle relaxant (succinylcholine). It can be treated symptomatically with analgesic agents such as aspirin, acetaminophen, or nonsteroidal anti-inflammatory drugs. Generally, muscle soreness decreases with subsequent treatments and is more common in younger patients. Severe symptoms can be managed by switching the paralytic agent to the nondepolarizing agent rocuronium, which has also been demonstrated to decrease post-ECT headaches (Saricicek *et al.* 2014).

Nausea is also a relatively common side effect of ECT. It may accompany a headache or occur independently. Nausea can be treated with prochlorperazine, ondansetron, or metoclopramide, which can be given prophylactically for susceptible patients.

Cardiovascular Side Effects

ECT is associated with an increased risk of cardiovascular complications in older adults who have, or who are at risk for, cardiovascular disease. Studies have found widely varying rates of cardiac complications in older adults undergoing ECT. The retrospective design of the studies, the lack of continuous cardiovascular monitoring, and the different definitions of what constitutes a cardiac complication probably account for the discrepancies in the results. Despite the inconsistencies, most studies have found a correlation between cardiac complications and age. ECT often produces transient systemic hypertension and abrupt transitions in cardiac rate, which can result in myocardial ischemia or arrhythmias. The higher incidence of cardiac complications among older adults is probably associated with the higher rate of preexisting cardiac conditions such as hypertension, coronary artery disease, and arrhythmias. On the basis of these observations, several authors have recommended the use of prophylactic cardiac medications to dampen cardiovascular responses during ECT in older adults who have (or are at risk for) cardiovascular disease.

Research has documented that labetalol (a medication with both a- and b-adrenergic blocking activity), esmolol (a shorter-acting b-blocker) (Castelli *et al.* 1995; Shrestha *et al.* 2007), and nicardipine (a calcium channel blocker) (Avramov *et al.* 1998; Zhang *et al.* 2005) can be safely used to attenuate the cardiac response during ECT.

It is recommended that adequate doses of an anticholinergic medication (intravenous atropine or glycopyrrolate) be used to decrease bradycardia induced by the initial stimulus (Swartz and Saheba 1989), and anticholinergic medications given before ECT have also been shown to increase cerebral oxygenation and perfusion during the seizure (Rasmussen *et al.* 2007). To help prevent ECT-induced hypotension, it is additionally recommended that all patients be adequately hydrated before undergoing ECT. If patients experience significant orthostatic hypotension in the recovery room, labetalol can be switched to the shorter-acting pure b-blocker esmolol.

The anesthetic agent propofol has been shown to have less cardiovascular effects than methohexital and can be used for patients with preexisting cardiac conditions requiring an attenuated hemodynamic response during treatment (Bailine *et al.* 2003). As noted earlier, the trade-off is a shortening of the seizure length with the use of propofol.

Cognitive Side Effects

The greatest area of concern with ECT among the lay public, patients, and their families is the potential development of adverse cognitive changes (Rajagopal *et al.* 2013).

The medical community's concerns about cognitive side effects and the negative images of ECT in the media are important factors determining the availability of ECT.

The technique by which ECT is administered influences the incidence and severity of cognitive side effects that may develop during a course of ECT. Specifically, electrode placement, the type of electrical waveform, the intensity of the electrical stimulus, and the frequency of ECT sessions all affect cognitive outcomes during ECT. Preexisting structural brain changes (e.g., white matter hyperintensities), medical illness, advancing age, low cognitive reserve (assessed in relation to education and occupation), and concomitant administration of certain psychotropic medications also may be risk factors for cognitive side effects from ECT (McClintock *et al.* 2014; Oudega *et al.* 2014).

It is important to recognize that depression itself (especially late-life depression) often causes cognitive deficits, such that successful treatment of depression with ECT often improves some aspects of cognition in certain patients (Weiner and Reti 2017). In depressed patients, Hihn *et al.* (2006) demonstrated that prefrontally mediated aspects of cognition, such as attention and immediate encoding, improved during ECT treatment of depression, whereas long-term memory functions remained impaired. In a review and metaanalysis, Semkovska and McLoughlin (2010) analyzed 84 studies that reported on post-ECT cognitive measures among a combined cohort of 2,981 patients; their findings included evidence that beyond 14 days after termination of the ECT course, several cognitive domains (processing speed, verbal working memory, and executive functioning) improved in comparison to pre-ECT cognition, presumably related to resolution of psychiatric symptoms that impaired cognition.

The memory loss sometimes observed after ECT can be both anterograde and retrograde and has a temporal gradient, being more prominent around the time of treatment course and continuing several weeks after the ECT course (American Psychiatric Association Task Force on Electroconvulsive Therapy 2001; Sackeim *et al.* 2000). Delayed recall is more affected than immediate recall, verbal more so than visual, and unstructured (e.g., random word lists) more so than contextualized (e.g., story recall) (Semkovska and McLoughlin 2010). In most patients any anterograde or retrograde memory problems clear quickly after ECT, as demonstrated in two pivotal National Institute of Mental Health trials (Kellner *et al.* 2010; O'Connor *et al.* 2001).

In rare cases the retrograde memory loss can be significant and may extend to events that occurred years before the ECT. There is a specific vulnerability of episodic/autobiographical memory to the effects of ECT, although autobiographical memory is also impaired by depression itself, and two recent reviews pointed out several methodological shortcomings in measures of autobiographical memory used in most ECT research to date (Brakemeier *et al.* 2011; Semkovska and McLoughlin 2013).

Evidence indicates that the degree of amnesia and global cognitive impairment incurred acutely during a course of ECT is greater with bitemporal ECT than with unilateral ECT (Lisanby *et al.* 2000; Semkovska and McLoughlin 2010), although this was not supported by a randomized trial comparing RUL, bifrontal, and bitemporal ECT, which showed only transient cognitive side effects with no significant differences based on electrode placement (Kellner *et al.* 2010). Evidence also suggests that cognitive side effects increase with the number of treatments administered, frequency of administration, and stimulus intensity (Sackeim *et al.* 2000; Shapira *et al.* 2000), although not all reports support these latter points (Semkovska and McLoughlin 2010).

Some long-term data also do not indicate that these acute differences in cognition in studies of unilateral versus bilateral ECT persist when assessed weeks to months after an ECT course. Although unilateral ECT is associated with fewer memory problems, the cognitive deficits that occur show a dose relationship and increase as the stimulus dose is increased to 8-12 times the seizure threshold (McCall *et al.* 2000; Semkovska and McLoughlin 2010). Research comparing bilateral and unilateral ECT has not addressed whether RUL ECT given at a dose of 10-12 times the seizure threshold would cause more cognitive side effects than bilateral ECT given at a dose that is minimally above or 1.5 times the seizure threshold. Bilateral ECT in this context generally refers to bitemporal electrode placement, but in a metaanalysis of bifrontal ECT for depression, Dunne and McLoughlin (2012) reported less global cognitive impairment with bifrontal (vs. bitemporal) ECT, on par with the overall global cognitive and amnestic effects of RUL ECT.

The causes of the memory disturbance associated with ECT are multifactorial and probably include the effects of anesthetic drugs, electrode placement, stimulus waveform, generalized seizures, and electrical dose (Sackeim *et al.* 2007). Because cognitive effects associated with ECT are perhaps the primary (rational) barrier to more widespread use of a highly effective treatment modality, not surprisingly researchers have started to explore ways to prevent or lessen these effects. In keeping with the possible cholinergic mechanisms of action of ECT-induced cognitive effects, at least three trials of acetylcholinesterase inhibitors (medications approved for treatment of certain dementias) have been reported in the literature, all small in sample size but all indicating benefit for general cognitive or memory-related test scores when the medications were administered during the acute phase of ECT (Matthews *et al.* 2013; Prakash *et al.* 2006; Stryjer *et al.* 2012). None of the trials reported any serious adverse events with these medications, which is notable considering theoretical concerns that cholinesterase inhibitors could cause prolonged paralysis when given with the muscle paralytic succinylcholine, commonly used in ECT anesthesia, and concerns that these medications could prolong the bradycardia or asystole that may immediately follow the electrical dose administration. Nonpharmacological efforts to mitigate cognitive side effects may also prove useful. Choi *et al.* (2011) reported positive early feasibility during ECT of a cognitive remediation intervention adapted from use among patients with mesial temporal lobe epilepsy.

Treatment-Emergent Mania

Switching to mania during a course of ECT, particularly in patients with a history of bipolar disorder, is rare but can occur (Angst *et al.* 1992). Although there is no established treatment once ECT-induced mania occurs (Lee *et al.* 2014), the best clinical approach is to stop ECT, start mood stabilizers, and reconsider the treatment plan. The best preventive treatment is to ensure that patients with a history of mania are on mood stabilizers during their acute course of ECT.

As discussed above, lithium is associated with an increase in the risk of delirium and prolonged neuromuscular blockade (Zolezzi 2016); however, stopping lithium before ECT will increase the risk of switching to mania. The treating clinician must determine the best course, which could include holding the evening dose of lithium the night before ECT in order to lower the blood level of lithium, switching temporarily to another mood stabilizer, or maintaining the lithium and monitoring for evidence of delirium.

The anticonvulsants used to treat mania (e.g., valproic acid, carbamazepine, topiramate, and lamotrigine) can increase the seizure threshold and potentially result in missed or abortive seizures. The antiepileptic medications have been shown in a retrospective study to result in higher seizure thresholds, shorter motor seizures, an increase in the number of failed seizures, and an increase in the maximum charge and number of treatments received (Virupaksha *et al.* 2010). However, this same retrospective study showed comparable symptom improvement in patients on and off antiepileptic medication. Other studies have found no effect of anticonvulsant medications on the efficacy of ECT or clinical outcomes (Jahangard *et al.* 2012; Rakesh *et al.* 2017). Using the methods-of-limit titration schedule can account for the increase in the seizure threshold, and the medications can be held the night before the treatment to decrease their effect on the seizure threshold. Another consideration could be to substitute an antipsychotic medication, which would have negligible effect on the seizure threshold and provide antimanic prophylaxis.

Postictal Agitation

Postictal agitation (PIA) can be a significant problem, with the potential for causing injury to both the patient and the nursing staff caring for the patient (Augoustides *et al.* 2002). PIA is difficult to predict in an individual patient and must be differentiated from status epilepticus. PIA is distinguished by the random flailing movements of the patient, in contrast to the rhythmic convulsions of a seizure, and by the fact that the patient does not lose consciousness or demonstrate the fixed gaze of a patient experiencing a generalized tonic-clonic seizure.

Several strategies are used in treating PIA, and most involve intravenous access. Midazolam or methohexital will often sedate the patient and can be very effective. Additionally, propofol can be used to manage PIA (Tzabazis *et al.* 2013). Intravenous haloperidol has been associated with ventricular ectopy (Greene *et al.* 2000) and should be used only for patients with cardiac monitors. The intramuscular atypical antipsychotic medications can be effective, with a more benign cardiac profile. Dexmedetomidine has been used to treat PIA in severe cases (Bryson *et al.* 2013; Cohen and Stewart 2013; O'Brien *et al.* 2010).

Preventive measures can also be taken. First, the use of an oral disintegrating atypical antipsychotic medication such as olanzapine at least 10 minutes before ECT can be very effective and does not require administration of any additional liquids (Hermida *et al.* 2016). Second, current drug use should be reviewed. Lithium has been associated with PIA and prolonged seizures (el-Mallakh 1988; Jha *et al.* 1996; Sadananda *et al.* 2013; Sartorius *et al.* 2005) and can be discontinued throughout the ECT course if clinically feasible or withheld the night before and morning of ECT treatments. Use of the anesthetic agent etomidate is also associated with PIA (Freeman 2009). Additionally, carbidopa has been linked to postictal delirium and should be withheld the morning of ECT treatment (Nymeyer and Grossberg 1997).

PIA has been correlated with increased serum lactate levels, and some have argued that increasing the succinylcholine dose to decrease ictal muscle activity and subsequent rises in serum lactate levels can decrease PIA (Auriacombe *et al.* 2000). Another strategy may therefore be to increase the succinylcholine dose if any muscle movement is present during the seizure. However, care should be taken because another potential cause of PIA is the patient awakening from anesthesia with latent paralysis

of the respiratory muscles. Patients describe this as very frightening and may question continuing ECT.

Interictal Delirium

Interictal delirium develops during a course of ECT and persists on days when the patient does not receive a treatment. This side effect is observed primarily in older adults and increases in incidence with advancing age (Figiel *et al.* 1990). ECT-induced interictal delirium is associated with prolonged hospitalization and an increased risk of falls. Among older adults, additional risk factors for interictal delirium are Parkinson's disease, Alzheimer's disease, one or more cardiovascular risk factors, and preexisting structural changes in the caudate nucleus observed on brain scans. Patients who develop postictal confusion are likely to have greater retrograde amnesia in the weeks and months after ECT (Sobin *et al.* 1995).

The incidence of delirium during a course of ECT can vary dramatically depending on the ECT technique used. As a rule, ECT-induced interictal delirium is a short-lived, reversible side effect if identified early. Once it has been identified, ECT treatments should be withheld until the delirium resolves. Subsequent treatments should be administered less frequently or at a lower electrical charge.

Effects of Electroconvulsive Therapy on Cerebral Physiology

Immediately after an ECT treatment, the EEG shows generalized slowing of brain wave activity. This slowing tends to increase and persist longer after successive treatments. After a course of ECT is completed, slow-wave activity gradually decreases, and EEGs show a reversion to baseline activity within 3 months (Weiner *et al.* 1986a). Rarely, electroencephalographic abnormalities may persist for more than 3 months. Prior electroencephalographic abnormalities may increase the risk for developing prolonged abnormalities after ECT, but the clinical significance of these abnormalities is unknown. Functional neuroimaging studies are consistent with post-ECT EEG findings of generalized slowing, especially in prefrontal regions. There is evidence from several studies of decreased cerebral perfusion and metabolism in frontal regions as well as decreased frontal connectivity with subcortical regions after a course of ECT (Abbott *et al.* 2014a); some postulate this is a possible mechanism of action for antidepressant effects of ECT, that is, quelling the "hyperconnectivity" that has been reported in frontal-subcortical circuits in MDD (Bolwig 2014).

Does Electroconvulsive Therapy Cause Brain Damage?

Human autopsy studies of patients who have received ECT have shown no convincing evidence of irreversible brain damage when ECT was administered with current techniques (Devanand *et al.* 1994; Oltedal *et al.* 2015; Scalia *et al.* 2007; Weiner 1984). These findings are supported by a brain MRI study in which no significant structural brain changes were found immediately or 6 months after the completion of ECT (Coffey *et al.* 1991). In a study of six depressed patients, cerebrospinal fluid markers of neuronal/glial degeneration (tau protein, neurofilament, and S-100 beta protein) were measured before and after a successful course of ECT and showed no biochemical evidence of neuronal/glial damage or blood-brain barrier dysfunction (Zachrisson *et al.* 2000). In fact, emerging evidence supports quite the opposite of these commonly held beliefs and fears among the public. ECS in animal studies has been associated with increased neurogenesis, synaptogenesis, angiogenesis, and gliogenesis, particularly in the hippocampus (Bouckaert *et al.* 2014). Human structural neuroimaging studies have revealed increased gray matter volume and increased hippocampal and amygdala volumes (Oltedal *et al.* 2017), increased volumes in frontolimbic areas (Gbyl and Videbech 2018), increased chemical markers of neurogenesis (Abbott *et al.* 2014b), and increased neuroplasticity (Bouckaert *et al.* 2014).

Prophylactic Somatic Treatment After Acute Response to Electroconvulsive Therapy

Although the short-term therapeutic benefits of ECT are clearly established, the 6-month relapse rate after ECT to treat depression remains high (Bourgon and Kellner 2000). Sackeim *et al.* (1990) followed 58 patients for 1 year after ECT and found a differential relapse rate of 64% in those with MDD (with and without psychotic features) in whom an adequate pre-ECT medication trial had failed. In contrast, the relapse rate in patients who did not receive an adequate pre-ECT antidepressant trial was only 32%. Other clinical and demographic factors, including the presence of delusions, were not significant in predicting relapse. The adequacy of the post-ECT maintenance medication did not correlate with relapse rates. However, post-ECT maintenance medications were not standardized, and the evaluation of the pre-ECT medication trial was retrospective. The conclusion of this study is intuitively appealing: Patients whose symptoms do not respond to antidepressant medication before ECT are those most likely to relapse with maintenance medication. With relapse occurring in almost two-thirds of such patients within 1 year after ECT, the relapse rate is alarmingly high.

In a prospective, randomized, double-blind trial, Sackeim *et al.* (2001) compared three maintenance strategies: placebo, nortriptyline (target steady-state level, 75-125 ng/mL), and nortriptyline plus lithium (target lithium steady-state level, 0.5-0.9 mEq/L). Over the 24-week trial, the depression relapse rate was 84% with placebo, 60% with nortriptyline, and 39% with nortriptyline plus lithium, indicating a statistically significant advantage for combination therapy. In another prospective study, Shapira *et al.* (1995) found that patients who responded to an acute course of ECT and subsequently underwent maintenance therapy with lithium for 6 months had a relapse rate of only 36%. Of the 22 patients in that study, the 8 who relapsed did so in the first 13 weeks. Several clinical factors were associated with relapse; these included a shorter duration of the index depressive episode, an additional depressive episode in the 12 months before ECT, and, again, failure of an adequate trial of antidepressant therapy before the ECT course.

The high relapse rates of depression in patients receiving antidepressant medications after a successful course of ECT have led clinicians to use alternative therapies, such as continuation or maintenance ECT, for patients who are at high risk for recurrence of their mood disorder. Continuation ECT is defined as ECT for up to 6 months after the acute ECT course (i.e., aimed at relapse prevention). Continuation ECT is differentiated from maintenance ECT, which is defined as ECT that continues for more than 6 months after the initial course (i.e., aimed at recurrence prevention).

The term *prophylactic ECT* is used to refer to any ECT treatments given as continuation or maintenance therapy. According to clinical guidelines, candidates for prophylactic ECT include individuals who have recurring affective episodes that are responsive to ECT and individuals who are resistant to, intolerant of, or noncompliant with antidepressant medications (American Psychiatric Association Task Force on Electroconvulsive Therapy 2001). The debate over appropriate prophylactic treatment for patients with an acute response to ECT has focused on the clinical decision to either continue therapy with antidepressant medications or initiate maintenance ECT.

The pivotal study in understanding this debate compared continuation pharmacology with nortriptyline and lithium to continuation ECT in 201 patients who had remitted with an acute course of bilateral ECT (Kellner *et al.* 2006). There was no statistical difference in the relapse rates, and more than half the patients in each group relapsed. This study demonstrates the high relapse rates after an acute course of ECT even with an aggressive pharmacological approach; however, the relapse rates in both groups were significantly lower than the relapse of patients in other studies on placebo controls. A metaanalysis suggested there was a modest efficacy of maintenance ECT with pharmacotherapy over pharmacotherapy alone (Elias *et al.* 2018).

The Prolonging Remission in Depressed Elderly (PRIDE) study evaluated the efficacy and tolerability of continuation ECT plus medication compared with medication alone in depressed geriatric patients after a successful course of ECT (Kellner *et al.* 2016a). This study demonstrated that tapering ECT after a successful acute course is effective in decreasing relapse after ECT.

A consensus conference from 2017 (Gill and Kellner 2019) summarized the evidence-based recommendations for maintenance treatment from the available data:

- The frequency of ECT sessions should be tapered after the patient responds to the acute course rather than stopped after they meet remission criteria.
- Electrode placement and pulse width during maintenance ECT should be the same as for the acute course. However, if a patient has an incomplete response, they may benefit from a more aggressive treatment during maintenance ECT if they show signs of relapse.
- Maintenance ECT should be combined with pharmacotherapy. Patients should be started on an antidepressant after an acute ECT course, and the maintenance antidepressant with the most data to support efficacy after ECT is nortriptyline, but venlafaxine is a good alternative. The antidepressant should not be one that had previously failed, which generally includes the antidepressants patients were on when they began their acute course of ECT.
- There is considerable evidence for the efficacy of lithium after ECT. Lithium augmentation is warranted if the patient has a history of treatment-refractory depression, bipolar disorder, bipolar diathesis (i.e., family history, atypical depression, hypomanic symptoms), psychotic depression, or significant suicidal risk or response, but not remission, to ECT. Lithium can be difficult to use while a patient is getting ECT because of the potential complication of lithium-induced delirium; however, patients can hold their dose of lithium before the ECT session to limit this potential side effect.
- The frequency of maintenance ECT should be individualized: "It is preferable to use a gradually decreasing frequency rather than a fixed frequency when commencing [maintenance ECT] for the first time for a patient, so as to find the lowest frequency at which that patient can remain well." Patients can be

"rescued" with additional ECT sessions when they show signs of relapse.

Investigational Procedures in Convulsive Therapies

A number of neuromodulation procedures are being investigated in mood disorders. These procedures exert their therapeutic effect by depolarizing neurons and initiating action potentials or modulating cell firing rates, resulting in the induction of neuroplastic changes in neural networks (Rossini *et al.* 2015). Three of these procedures are convulsive: iLAST dosing therapy, MST, and FEAST. These procedures are designed to induce seizures with more focal stimulation of the cortex than ECT and potentially produce a therapeutic seizure with fewer cognitive side effects.

iLAST involves titrating the seizure dose by adjusting the current amplitude to determine the seizure threshold (Radman and Lisanby 2017). This technique decreases the neuroanatomic area of the seizure and therefore decreases the spread of the seizure to cognitively sensitive brain structures such as the amygdala and hippocampus. Typically the seizure threshold titration procedure keeps the current amplitude constant at 800-900 mA and adjusts the frequency (or seizure length) to determine the seizure threshold. The iLAST technique is based on the fact that the electric field strength of 800-to 900-mA amplitude is significantly above what is required to induce a seizure and produces a nonfocal seizure that potentially increases cognitive side effects (Deng *et al.* 2011).

MST uses high-intensity, rapidly fluxed magnetic fields to produce seizure-inducing electrical currents in the brain. MST delivers a very-high-frequency stimulus (e.g., 100 Hz) that results in an electrical field that is more focal and superficial than ECT (Deng *et al.* 2011). The stimulus has less of a direct effect on the mesial temporal structures (e.g., hippocampus) and theoretically is associated with fewer cognitive side effects than ECT. To date, there are only small nonrandomized trials evaluating the efficacy of MST. MST was shown to be equivalent to ECT in one study (Kayser *et al.* 2011), although another study showed a less robust response (Fitzgerald *et al.* 2013). MST's cognitive safety has been either equivalent to (Fitzgerald *et al.* 2013; Kayser *et al.* 2011) or better than that of ECT (Lisanby *et al.* 2003; Polster *et al.* 2015).

The electrical stimulus used in FEAST technology induces more focal seizures in the prefrontal cortex by changing the ECT bipolar pulse to a monopolar pulse through use of a smaller anode (positive electrode) placed frontally and a larger cathode (negative electrode) on the vertex (Nahas *et al.* 2013). A SPECT scan of a patient undergoing FEAST demonstrated increases in regional cerebral blood flow that were limited to the right prefrontal cortex and postictal changes that generalized bilaterally (Chahine *et al.* 2014). A small open-label study supported an antidepressant effect (Nahas *et al.* 2013); however, future studies are needed to support this novel approach to convulsive therapy.

Conclusion

Nearly 80 years have passed since ECT was first used in the treatment of psychiatric disorders. The scientific evidence for the safety and efficacy of ECT has grown exponentially, and no available medical treatment is as effective in treating debilitating, life-threatening illnesses in a number of psychiatric disorders, including treatment-resistant depression, mania, catatonia, and schizophrenia. Other neuromodulation techniques, both convulsive and subconvulsive, hold promise for elucidating neuroanatomic pathways and increasing the available treatments for mood disorders. Further research is needed to elucidate which biomarkers and patient variables are associated with response to each of these treatments. However, for patients with severe, treatment-resistant mood disorders and schizophrenia, ECT remains the gold standard.

CHAPTER 47

Psychedelic Drugs as Treatments in Psychiatry

David Nutt, FRCP, FRCPsych, FBPhS, FMedSci, D.Laws.
David Erritzoe, M.D., Ph.D., MRCPsych

Over the past 20 years there has been a resurgence of interest in the therapeutic potential of several classes of currently illegal drugs, particularly serotonergic psychedelics such as psilocybin, lysergic acid diethylamide (LSD), and dimethyl tryptamine (DMT) plus the entactogen 3,4-methylenedioxymethamphetamine (MDMA) (Nutt *et al.* 2020). The psychedelics are natural or seminatural molecules that are agonists of the serotonin type $_{2A}$ (5-HT$_{2A}$) receptor. In the 1950s and 1960s some were used therapeutically in psychiatry with a huge investment from National Institutes of Health that led to many hundreds of publications on LSD and a lower but still significant number on psilocybin.

They were used to treat a range of "neurotic" disorders, especially anxiety and depression, and some substance use disorders. Dosing took two forms: a high-single-dose treatment that produced a trip from which the person might emerge with a very different mindset (psychedelic therapy) and a lower dose that was used before each psychotherapy session to help break down the patient's resistance to engaging with their issues (psycholytic therapy). Clinical results from both treatment modalities were seen as generally very powerful and effective, with a low level of adverse effects. Problems such as psychosis and suicidality were rare, probably lower than in the populations treated with other approaches or left untreated (Passie *et al.* 2008).

The best-known results in treating substance use disorders came from the work of Bill Wilson (the founder of Alcoholics Anonymous), who said he escaped from the chains of his addiction as a result of a trip. Wilson's own experience led him to promote the use of LSD in the treatment of alcohol use disorder, and six trials were conducted before the drug was banned. A modern meta-analysis of these data by Krebs and Johansen (2012) found LSD to be more efficacious than any current therapy.

LSD, psilocybin, and most chemically related serotonergic agonist compounds were banned in the late 1960s. They were all put into Schedule I and so defined as having no accepted medical value and but significant potential for harm and dependence. This scheduling stopped research on psychedelics for over 40 years, and only in the past decade have attempts been made to reverse this scheduling. Because of their illegal status and because the National Institutes of Health stopped funding studies, research with these compounds nearly disappeared. In the current century, a few psychotherapy studies and human neuroimaging research on brain mechanisms have revealed the effects of these compounds on the brain, especially in regions that are thought to underpin depression, and these findings have led to a resurgence in interest and investment. (Note: Ketamine can have psychedelic effects, but its pharmacological target is glutamate [see Chapter 21, "Ketamine and Esketamine"].)

MDMA is a synthetic molecule, related to methamphetamine, that in the 1970s was synthesized and tested by Alexander Shulgin, who reported it as having special pro-empathy (entactogenic) properties. For this reason, psychotherapists on the West Coast of the United States began using MDMA, especially in couples counseling, where its entactogenic effects allowed couples to reexperience the affection that was present at the start of their involvement and to rebuild a failing relationship. At that time, MDMA was called Empathy and was legal (whereas many other amphetamine derivatives were already illegal), and this status gave rise to its recreational use in clubs and raves, under the name Ecstasy. A media and political backlash resulted, and the ensuing pressure led to MDMA being banned and treatment with Empathy being stopped.

Drugs Used in Psychedelic Trials

Almost all modern clinical research has been conducted with psilocybin, the active ingredient of magic mushrooms. In the body it is converted to psilocin, a 5-HT_{2A} receptor agonist that mediates its mind-altering properties. Its effects are rarely overwhelming, so they are somewhat easier to cope with than those of LSD or DMT. The effects of psilocybin taken orally last 4-6 hours, whereas those of LSD can last 12 hours or more, necessitating overnight stays for study participants.

DMT, when in its pure form, has to be given intravenously (or smoked) and has an effect lasting just a few minutes, which may not be long enough for useful therapeutic insights to develop. However, the intravenous infusion of the DMT can be extended to make the drug delivery and the associated psychedelic experience last longer, which could carry value. DMT is also used in the form of ayahuasca, a drink that is legal in a number of countries in Central and South America for religious and healing purposes. Ayahuasca contains two important plant products, one of which is DMT. The other is harmaline, a monoamine oxidase inhibitor that blocks this enzyme in gut and liver and so allows the DMT in the drink to get to the brain. Human neuroimaging studies of ayahuasca have shown it to have effects similar to those of psilocybin and LSD, and several open clinical trials using ayahuasca have been conducted in patients with depression. However, Western medicine has not yet adopted ayahuasca because its plant ingredient concentrations are hard to control, and the coadministration of a monoamine oxidase inhibitor is risky for some individuals (e.g., those on selective serotonin reuptake inhibitors [SSRIs]). To overcome these problems, several pharmaceutical companies are developing infusions of synthetic DMT. Also, the related compound 5-methoxy-N,N-dimethyltryptamine, a powerful short-acting psychedelic, is being developed for clinical evaluation, as are synthetic analogs of both psilocybin and LSD.

Ibogaine is a plant alkaloid from West Africa that is used in a number of countries as an unlicensed treatment for substance use disorders, especially those involving heroin, although there are no high-quality studies. Some deaths have been reported, probably due to QTc prolongation. This cardiac effect has limited research, and its effects on the brain are not yet characterized. An active metabolite, nor-ibogaine, is being developed as a possibly safer alternative.

Twenty-First-Century Resurrection of Psychedelics and MDMA in Psychiatry

Psychedelics

Over the past two decades, research on psychedelics has restarted for two reasons: the discovery of their novel effects on the brain and positive findings from small exploratory clinical studies. Neuroimaging results of functional MRI and magnetoencephalography reveal a disruption of brain activity in many regions but particularly the default mode network and the subgenual cingulate cortex. Various successful treatments of depression--from electroconvulsive therapy and deep brain stimulation to antidepressant drugs, psychotherapy, and even placebo--have been associated with reductions in subgenual cingulate cortex activity, supporting the view that this region is a key node in driving depression (Zhou *et al.* 2017). Other functional MRI imaging studies have found the default mode network to be overactive in depression (Zhou *et al.* 2020).

The first modern clinical trial of any psychedelic was by Moreno *et al.* (2006), who gave nine subjects with treatment-resistant OCD up to four different dosages of psilocybin in an open-label design (Table 47-1). A few years later, Grob *et al.* (2011) conducted a double-blind, crossover study in which a moderate (0.2 mg/kg) dose of psilocybin and an active placebo (niacin 250 mg) were given to 12 patients with advanced-stage cancer diagnoses that had resulted in acute stress or anxiety disorders as defined by DSM-IV (American Psychiatric Association 1994).

TABLE 47-1. Psilocybin studies: depression and related disorders

Study	Study type	Target illness	*N*	Primary outcome measure(s)	Main result	Control condition(s)
Moreno *et al.* 2006	Open label, up to four	OCD	9	Y-BOCS	Two-thirds showing	Very low dose

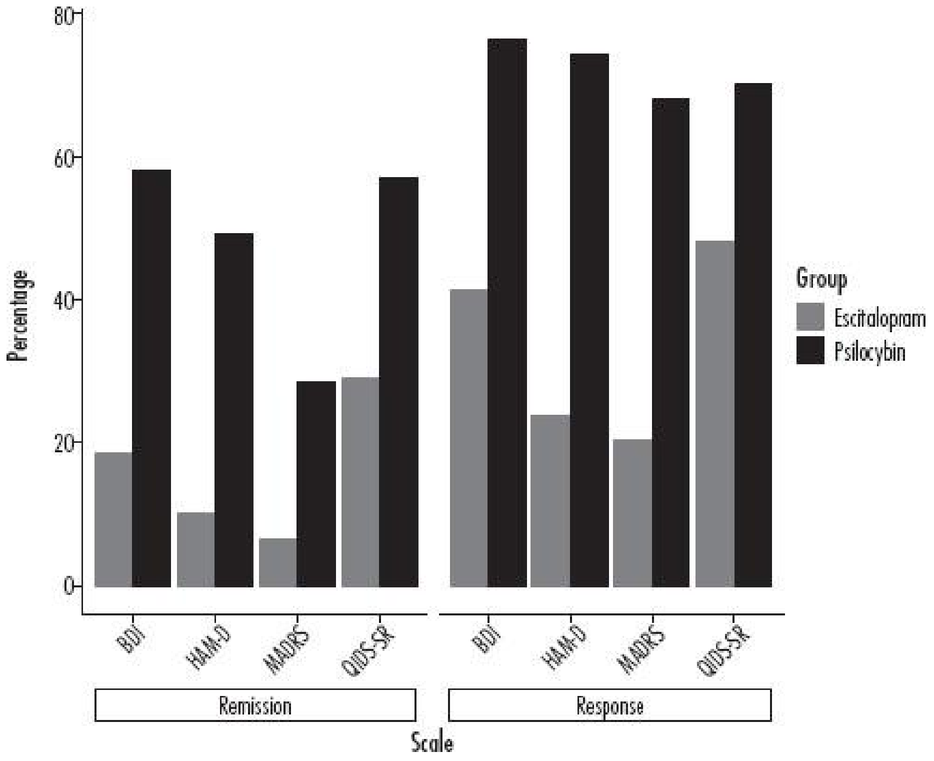

FIGURE 47-1. Response and remission rates for psilocybin versus escitalopram at week 6: comparative trial in 59 patients with long-standing depression.

See study description in text. Response (baseline to 6 weeks, all scales) was defined as > 50% reduction in scores. Remission (6 weeks) was defined as a QIDS-SR score of [?] 5, a BDI score of [?] 8, a MADRS score of < 10, and a Ham-D score of [?] 7. BDI = Beck Depression Inventory; Ham-D = 17-item Hamilton Rating Scale for Depression; MADRS = Montgomery-Asberg Depression Rating Scale; QIDS-SR = 16-item Quick Inventory of Depressive Symptomatology-Self-Report.

Source. Data from Carhart-Harris *et al.* 2021.

More recently, two studies of psilocybin in major depressive disorder (MDD) were conducted by the UK Imperial College team of Nutt and Carhart-Harris. In the first, an open-label study of patients with treatment-resistant depression, subjects were given first a low (10 mg test) and then a high (25 mg) oral dose of psilocybin (Carhart-Harris *et al.* 2016, 2017). In this study, patients had very-long-standing MDD (mean duration 17.7 years +- 8.4 years) that usually had been resistant to multiple treatments (mean number of failed medications: 4.6 +- 2.6). The primary outcome measure was the mean change in depression ratings on the Quick Inventory of Depressive Symptomatology-Self-Report (QIDS-SR). Highly significant improvements in QIDS-SR depression ratings were seen at all time points up to 6 months, with the maximal effect seen at 5 weeks (Cohen's *d* = 2.3).

Subsequently, the Imperial College group conducted a comparative trial of psilocybin versus the SSRI escitalopram in 59 patients with long-standing, moderate to severe MDD (Carhart-Harris *et al.* 2021). About half of the patients were weaned off antidepressants and half were drug-free. The psilocybin group (n = 30) received two 25-mg doses of psilocybin given 3 weeks apart plus 6 weeks of daily placebo, and the escitalopram group (n = 29) received two 1-mg doses of psilocybin given 3 weeks apart plus 6 weeks of daily oral escitalopram (10 mg daily for 3 weeks, then 20 mg for another 3 weeks). The primary outcomes were mood and well-being changes from baseline at 6 weeks. Well-being was significantly improved by both treatments, but was more improved with the high-dose (25 mg) psilocybin. Depression scores also improved with both treatments, and although the primary measure--change in QIDS-SR--did not differentiate the groups, all other mood measures favored psilocybin, as did the remission rates (Figure 47-1).

In the United States, Davis *et al.* (2021) conducted a psilocybin treatment study in MDD and found similar results. Twenty-seven patients underwent two psilocybin sessions (session 1, 20 mg/70 kg; session 2, 30 mg/70 kg) in the context of supportive psychotherapy. Depressive symptom ratings showed rapid decreases from baseline to day 1 after session 1 (from a mean [SD] QIDS-SR score of 16.7 [3.5] to 6.3 [4.4]; Cohen's d = 3.0), and ratings remained statistically significantly reduced through the week 4 follow-up.

In addition to Grob *et al.* (2011), there have been two other controlled studies of the use of psilocybin for anxiety and depression associated with life-threatening illness. In the United States, Griffiths *et al.* (2016) treated 51 patients with anxiety and depressive symptoms resulting from a life-threatening cancer diagnosis. Placebo was a very low (ineffective) dose of psilocybin (1 mg or 3 mg/70 kg) compared with the much higher active-treatment dose (22 mg or 30 mg/70 kg). Administration was counterbalanced with 5 weeks between sessions, and the study included a 6-month follow-up. The Hamilton Rating Scale for Depression (Ham-D) and the Hamilton Anxiety Scale were the primary outcome measures and showed superiority for the high dose versus the low dose at 5 weeks. The placebo group was then crossed over to a high dose, and these patients experienced significant improvements also.

Similarly, Ross *et al.* (2016) gave 29 patients with cancer-related anxiety and depression a single dose of 0.3 mg/kg psilocybin or 250 mg niacin as active placebo, with crossover at 7 weeks. The group receiving psilocybin showed clinical benefits, as measured by both clinician-and patient-rated scales, that lasted up to the crossover at 7 weeks and were then sustained for up to 8 months. The active-placebo group showed transient improvements, but these were not sustained, although these patients also showed immediate and sustained reductions in anxiety and depression scores after switching to psilocybin.

Another depression study was recently reported from Switzerland by von Rotz *et al.* (2023). It was a double-blind, randomized controlled trial (RCT) of 52 participants diagnosed with MDD who received either a single moderate dose (0.215 mg/kg body weight) of psilocybin or placebo in conjunction with psychological support. Two weeks after the intervention, participants in the psilocybin condition (*n* = 26) showed an absolute decrease in symptom severity of [?]13.0 points compared with baseline, which was significantly larger than the decrease seen in the placebo condition (*n* = 26). Among participants in the psilocybin condition, 14 of 26 (54%) met the MADRS remission criteria.

Additionally, in Switzerland, Gasser *et al.* (2015) performed a trial with LSD at either a low (20 mg) or a high (200 mg) dose for 10 patients with depression and trauma. The positive outcomes from this study led to this drug being made available for compassionate use in that country.

There have been several open trials of ayahuasca in depression, but the first RCT was conducted by Palhano-Fontes *et al.* (2019), who found a fast onset of effects and powerful reductions in depressive symptoms. In this study, 29 patients with moderate to severe treatment-resistant (Ham-D [?] 17) depression received either ayahuasca (0.36 mg/kg of DMT, *n* = 14) or placebo (a sour and bitter-tasting inert liquid, *n* = 15).

Building on the reports of the utility of psychedelics in alcohol use disorder from Wilson, the Johnson/Griffiths team at Johns Hopkins conducted an open study in which 15 people trying to stop smoking tobacco were treated with psilocybin 25 mg three times during a 20-week quitting course (Table 47-2). At 6 months, 12 of the 15 subjects had become smoking-free, and at 12 months, 10 of the 15 subjects remained smoking-free, a much better outcome than current smoking-cessation medicines (Johnson *et al.* 2017).

TABLE 47-2. Psilocybin studies: substance use disorders

Study	Study type	Target illness	*N*	Primary outcome measure(s)	Main result	Control condition(s)
Johnson *et al.* 2014, 2017	Open label, two fixed doses (20 and 30 mg/ 70 kg) and a third optional	Tobacco dependence	15	Abstinence	12 patients (80%) fully abstinent at 6 months, 10 at 12 months, and 9 at 30 months.	None
Bogenschutz *et al.* 2015	Open label, two or three fixed doses (0.3-0.4 mg/kg)	Alcohol dependence	10	Reduced heavy drinking days	Heavy drinking days significantly reduced during weeks 5-12 vs. baseline as well as vs. weeks 1-4.	None
Bogenschutz *et al.*	Double-blind,	Alcohol dependence	93	Reduced heavy	Reduction in heavy	Active placebo:

Note. DPH = diphenhydramine.

Study	Study type	Target illness	*N*	Primary outcome measure(s)	Main result	Control condition(s)
2022	two doses (25-40 mg/70 kg) in randomized phase. Offered single dose in open-label phase after 36 weeks.	nce		drinking days	drinking days during 32-week double-blind period significantly larger for psilocybin group vs. DPH group (23.6% vs. 9.7%).	DPH (50-100 mg)

Note. DPH = diphenhydramine.

Another study of psilocybin, involving 10 patients with DSM-IV-defined alcohol dependence, was conducted by Bogenschutz *et al.* (2015) at the University of New Mexico (see Table 47-2). Participants received two psilocybin treatments in addition to a standard psychotherapy course and demonstrated a marked reduction in heavy drinking days with psilocybin.

The Bogenschutz group recently reported a much larger double-blind RCT of two doses of psilocybin versus two doses of an active placebo, the antihistamine diphenhydramine (Bogenschutz *et al.* (2022). A total of 95 participants with alcohol use disorder were randomly assigned to psilocybin (*n* = 49) or diphenhydramine (*n* = 46). The main outcome measure was percentage of heavy drinking days during the 32-week double-blind period. Patients receiving psilocybin had a significantly lower percentage of heavy drinking days (9.7%) compared with those receiving diphenhydramine (23.6%), a mean difference of 13.9% (95% CI, 3.0-24.7; *P* = 0.01). Mean daily alcohol consumption (number of standard drinks per day) was also lower in the psilocybin group (see Table 47-2).

MDMA

Although MDMA is not a psychedelic in the traditional sense of the word, it does have profound effects that allow people insights into their psychiatric problems and has proved especially helpful in the treatment of PTSD (Table 47-3). Several studies run by the Multidisciplinary Association for Psychedelic Studies (MAPS) have demonstrated that a couple of sessions of exposure therapy under MDMA (usually 125 mg with a 62.5-mg booster after 2 hours) can have powerful therapeutic effects (Mithoefer *et al.* 2011, 2018). Based on these positive findings, both the FDA and European Medicines Agency gave their approval for multicenter studies in the United States and Europe, and the first of these was reported in 2021 (Mitchell *et al.* 2021). If the next one is similarly positive, then it seems likely that MDMA will also become an approved medicine sometime in the 2020s. In addition, preliminary UK data recently showed promise for MDMA-assisted therapy for the treatment of alcohol dependence (*n* = 14 [Sessa *et al.* 2021]) (see Table 47-3).

TABLE 47-3. MDMA studies: PTSD and alcohol use disorder

Study	**Study type**	**Target illness**	***N***	**Primary outcome measure(s)**	**Main result**	**Control condition(s)**
Six MAPS Phase II PTSD trials (Jerome *et al.* 2020), #12124	Double-blind RCTs; two doses (range: 75-125 mg)	PTSD	103	Reduced CAPS score	Majority of patients entered remission, symptom improvements continued at least 12 months after end of treatment.	Placebo/control doses (0-40 mg, *n* = 31)
MAPS Phase III trial	Double-blind RCT,	PTSD	90	Reduced CAPS score	Very large effect size at 2 months.	Placebo

Note. CAPS = Clinician-Administered PTSD Scale; MAPS = Multidisciplinary Association for Psychedelic Studies; RCT = randomized controlled trial.

Study	Study type	Target illness	*N*	Primary outcome measure(s)	Main result	Control condition(s)
(Mitchell *et al.* 2021), #11859	3 doses					
Sessa *et al.* 2021	Open label, two doses (187.5 mg)	Alcohol use disorder	14	Drinking level	Large reduction in drinking for up to 9 months in majority of patients.	Not applicable

Note. CAPS = Clinician-Administered PTSD Scale; MAPS = Multidisciplinary Association for Psychedelic Studies; RCT = randomized controlled trial.

Clinical Perspectives

Treatment with psychedelics and MDMA is more complex than conventional antidepressant or anti-addiction therapies, requiring psychotherapy with the administration of the drug. Many consider it a new form of treatment in psychiatry: drug-assisted psychotherapy (or psychotherapy-assisted drug treatment). Before being given the drug, patients need to be prepared for the powerful psychological experience of the psychedelic/MDMA session. This process involves at least one dedicated preparatory session with a trained therapist (often called a guide) in which the patient is educated about the rationale and procedure of the drug administration session and is reassured that they will be looked after throughout it.

The drug session itself is usually done in an environment that optimizes patient comfort and security, usually a pleasantly decorated and softly lit room as opposed to a traditional medical clinic. Patients are given eye-shades so they can better explore inner visual experiences, and in most studies music is available through headphones. At least one, and ideally two therapists or guides are present in the room for the trip duration (ideally one male and one female). They are there to provide reassurance and medical cover in case of a bad trip.

With psychedelic drug sessions, the therapists or guides talk with the patient only if the patient needs reassurance, which often they do not. It is important to note that there is no expectation of conversation during the trip and no direction of the patient's thinking by the therapists.

On the next day and subsequent days, in what are called integration sessions, the contents and experiences of the trip are discussed with the therapists who facilitate psychotherapeutic insights and behavior change. Often additional integration visits (typically two to four in total) are part of the study design. There is as yet no standard psychotherapeutic method for psychedelic therapy, but many groups use mindfulness-or acceptance-based therapies, such as Acceptance and Commitment Therapy (Hayes and Wilson 1994) or Watts's Accept, Connect, and Embody model (Watts and Luoma 2020).

An important difference between psychedelic-and MDMA-assisted therapy is that therapists or guides are more actively engaged during a therapeutic session with MDMA than with psychedelics, because therapeutic material, such as trauma, is discussed actively during the MDMA session.

Group treatment has some logistic benefits and is being used in some retreats that use ayahuasca for PTSD. Historically, LSD has been used effectively in group therapy, and the biotechnology company COMPASS Pathways has conducted group sessions with psilocybin to accelerate the training of therapists.

A major clinical issue relevant to the use of both psychedelics and MDMA is that the therapeutic effects are blunted in people taking SSRI antidepressants, probably through receptor desensitization. Similarly, their effects and hence efficacy are reduced in patients treated with 5-HT_{2A} receptor blocking drugs (e.g., antipsychotic drugs such as quetiapine and olanzapine and antidepressants such as mirtazapine). Therefore, to optimize therapeutic effects it is best to discontinue these medications before administering psychedelics or MDMA. But this needs to be done with care to reduce the risk of worsening the underlying depression or producing discontinuation reactions.

Duration of Action

For some patients the impact of just one or two dosing sessions can be very long-lasting (Andersen *et al.* 2021), allowing the prospect of a cure to be considered. For others the beneficial effects seem to wane over time, probably because the brain processes underlying these disorders, which are often decades old, have become deeply ingrained in the brain. For patients who experience relapse, follow-up treatments are now being explored, but the illegal status of these drugs in most countries makes their use outside clinical trials almost impossible, except in a few countries (e.g., Canada and Switzerland, where compassionate use is now allowed). In July 2023, regulators in Australia agreed to reschedule psilocybin and MDMA to make them available for

people with treatment-resistant depression and people with treatment-resistant PTSD, respectively (Therapeutic Goods Administration 2023).

Safety Concerns

Although the claims of harms that were used to justify the banning of psychedelics and MDMA were largely spurious, there is no question that the psychedelics have powerful effects on the mind and can take patients into challenging places relating to memories of past trauma. There is also the risk of precipitating or worsening psychosis (De Gregorio *et al.* 2016), and so these treatments are currently avoided in patients with a history of psychosis (and in first-degree family members); so far, patients with bipolar depression have not been treated in case mania might be induced. Note that if they are too challenging, the effects of psychedelics can be terminated with a benzodiazepine or an antipsychotic with 5-HT$_{2A}$ receptor blocking activity, such as risperidone or olanzapine.

Whereas the safety and potential neurotoxicity of recreational MDMA (Ecstasy) use has been controversial among scientists for decades, one-time or short-term use in the context of therapy is generally considered safe (Mitchell *et al.* 2021; Sessa *et al.* 2019). Acutely, an MDMA experience may include transient cognitive and executive deficits affecting verbal and spatial memory and processing speeds (Hanson and Luciana 2004). In addition, transient mild to moderate muscle tightness (especially of the jaw), decreased appetite, nausea, hyperhidrosis, and feeling cold have been reported in trials of MDMA-assisted therapy (Mitchell *et al.* 2021). When used recreationally, MDMA (but not psychedelics) has been associated with reversible (estimated to return to normal levels after about 200 days of abstinence) brain reductions of the serotonin reuptake transporter, but only among people who had used the drug more than about 50 times in their lives (Erritzoe *et al.* 2011). Importantly, recreational Ecstasy use often involves mixed use with other substances or impure samples of MDMA, which makes it hard to precisely estimate its harm outside a controlled lab or clinic setting. When ranked by experts with a range of other legal and illegal substances (including cannabis, heroin, and alcohol), Ecstasy is positioned at the less harmful end of the spectrum (Nutt *et al.* 2010; van Amsterdam *et al.* 2010, 2015). However, it is important to note that deaths attributed solely to recreational intake of MDMA have been reported (Schifano *et al.* 2003).

Brain Mechanisms

The current thinking with psychedelics (and perhaps MDMA also) is that they disrupt the maladaptive repetitive cognitive and behavioral circuits that underpin depression, PTSD, and substance use disorders. The trip itself may give patients a new view of a world without depression or addictive disorders and insights into the reasons for their illness that they can refute or reframe. Also, both psychedelics (Ly *et al.* 2020) and MDMA (Rozas *et al.* 2004) can increase neuroplasticity, which may facilitate psychotherapy and allow the brain to reset itself into a new, illness-free state.

There is growing evidence that the depression-lifting effects of psychedelics are mediated in quite a different way from those of antidepressant drugs such as the SSRIs. The SSRIs seem to protect against stress by enhancing serotonin function at the 5-HT$_{1A}$ receptor, thus making the patient more resilient (Carhart-Harris and Nutt 2017). Psychedelics acting via the 5-HT$_{2A}$ receptor are believed to reset the brain processes that underpin depressive thinking and so allow the patient to work through their issues and overcome their depression (Carhart-Harris and Nutt 2017).

MDMA works differently, as it releases serotonin by blocking (and even reversing) the action of the presynaptic serotonin reuptake transporter and also possesses some direct 5-HT$_2$ receptor agonism (Green *et al.* 2003). In addition, MDMA blocks tryptophan hydroxylase (i.e., inhibits synthesis of serotonin) (Schmidt and Taylor 1987) and increases cortisol, oxytocin, vasopressin, and dopamine levels (Colado *et al.* 2004; Parrott *et al.* 2008; Wolff *et al.* 2012). Functional MRI studies have located its main site of activity in the limbic system, where it suppresses activity especially of the amygdala and hippocampus (Carhart-Harris *et al.* 2015). It is believed that this damping down of the emotional memory circuits helps patients relive their traumas without being overwhelmed by the emotions that accompany these memories. The emotional responses can then be extinguished as the patient gets mastery of them (Nutt and de Wit 2021).

Microdosing

Microdosing is a term for the use of subpsychedelic and even subdetectable doses of psychedelics (not MDMA), usually 5%-10% of full psychedelic doses. Microdosing has become popular with people in the creative industries, who think it improves their creativity. Others claim it helps reduce stress, depression, and anxiety. Microdoses are taken regularly, usually a couple of times a week over months (Kuypers *et al.* 2019). However, because these drugs are illegal there is no way of knowing for sure what exactly is being taken. The best controlled trial so far used a novel "self-blinding" approach and found that the effect of LSD and psilocybin microdosing was probably mostly due to expectation (Szigeti *et al.* 2021). However, new, more controlled trials are being set up.

Future Directions and Research Needs

In the past few years there has been a massive expansion in research on psychedelics (and to a lesser extent MDMA) due to significant investments by companies that have been set up to develop these drugs as medicines. Controlled trials of psilocybin in other forms of depression, OCD, anorexia nervosa, and various substance-related and addictive disorders are under way, as well as some studies using LSD or DMT. But many key questions are still unresolved.

One question is the efficacy and safety of these drugs in other disorders, especially eating disorders (including anorexia nervosa and food addiction in obesity), chronic pain conditions (including fibromyalgia), and behavioral addictions (including gambling disorder). With an appropriate level of assisting therapy, disorders with the potential to benefit from psychedelics may also include difficult-to-treat conditions such as borderline personality disorder (also called emotionally unstable personality disorder) and depression in bipolar II disorder.

The optimal duration of the trip for therapeutic benefit is still uncertain and is the subject of ongoing research. One company is developing a 5-HT$_{2A}$ receptor antagonist to shorten the duration of therapeutic LSD trips. Another is exploring an intravenous infusion of DMT to increase the therapeutic duration. Others are exploring new routes such as nasal and buccal administration for DMT-like compounds. A related question is the extent to which psychotherapy is needed, because some people report clinical value when self-medicating.

An interesting neuroscientific question is whether the therapeutic activity of psychedelics can occur without a trip. Earlier work has shown that lower (subtrip) doses are less effective, but the complexity of the 5-HT$_{2A}$ receptor's postsynaptic messaging makes it possible to make agonists that activate the receptor without being psychedelic. Recent preclinical research has shown that it is possible to make 5-HT$_{2A}$ agonists that have antidepressant-like properties in rodents but do not produce the head twitch response, which in rodents is characteristic of drugs with psychedelic activity in humans. Time will tell whether or not they are psychedelic in humans and whether they are as effective as antidepressants as the classic psychedelics.

PLATES 2 AND 3. ***(Figure 1-9)*** **Optogenetic manipulation of neural circuits** ***(opposite page).***

(I) Direct stimulation of neuronal cell bodies is achieved by injecting virus at the target region and then implanting a light-delivery device above the injected region. Even this simple experiment can provide specificity with viruses that will not transduce afferent axons and fibers of passage. **(II)** Additional cell-type specificity is attained either by cell-type-specific promoters in the viral vector or via a recombinase-dependent virus, injected in a transgenic animal expressing a recombinase such as Cre in specific cells, leading to specific expression of the transgene only in defined cell types. **(III)** Projection (axonal) targeting is achieved by viral injection at the region harboring cell bodies, followed by implantation of a light-delivery device above the target region containing neuronal processes from the virally transduced region; in this way, cell types are targeted by virtue of their projections. **(IV)** Projection termination labeling is a more refined version of projection targeting, in which cells are targeted by virtue of synaptic connectivity to the target region, with likely exclusion of cells whose axons simply pass through the region. Transcellular labeling using a recombinase-dependent system is shown. Viruses expressing Cre fused to a trans-neuronal tracer (lectin) are delivered at the synaptic target site, and a Cre-dependent virus is injected into the region with cell bodies. Cells that project to the Cre-injected area express the Cre-dependent virus and become light sensitive. Transcellular labeling can also be achieved with axon terminal-transducing viruses, although without control over the postsynaptic cell type. **(V)** Expression of two opsins with different characteristics in one brain region using a combination of promoter-or Cre-based approaches. Light delivery to the somata is performed using two different wavelengths designed to minimize cross-activation. **(VI)** Projections from two different brain regions are differentially stimulated with two wavelengths matched to the respective opsins expressed upstream.

PLATE 4. ***(Figure 2-2)*** **Ion channel function in the CNS.**

The plasma membrane Na$^+$/K$^+$ ATPase establishes a concentration gradient in the CNS, pumping Na$^+$ out and K$^+$ into the cell. Ion channels permit the passive diffusion of ions across the plasma membrane. Thus, opening of Na$^+$ channels depolarizes--and of K$^+$ channels hyperpolarizes--a neuron. ADP = adenosine diphosphate; ATP = adenosine triphosphate; mV = millivolt.

PLATE 5. ***(Figure 2-4)*** **Diversity of G protein-coupled receptors (GPCRs) signaling.**

A wide variety of ligands, including biogenic amines, amino acids, ions, lipids, peptides, and proteins, use GPCRs to stimulate cytoplasmic and nuclear targets through heterotrimeric G-protein-dependent and -independent pathways. Such signaling pathways regulate key biological functions such as cell proliferation, cell survival, and angiogenesis. 5-HT = 5-hydroxytryptamine; C = carboxy terminus; cAMP = cyclic adenosine monophosphate; E1, E2, E3 = extracellular loop 1, 2, 3; DAG = diacylglycerol; FSH = follicle-stimulating hormone; GDP = guanosine diphosphate; GEF = guanine nucleotide exchange factor; GTP = guanosine triphosphate; I1, I2, I3 = intracellular loop 1, 2, 3; LH = luteinizing hormone; LPA = lysophosphatidic acid; N = amino terminus; P = phosphorus; PAF = platelet-activating factor; PI3K = phosphatidylinositol 3-kinase g; PKC = protein kinase C; PLC-b = phospholipase C-b; S1P = sphingosine-1-phosphate; TSH = thyroid-stimulating hormone.

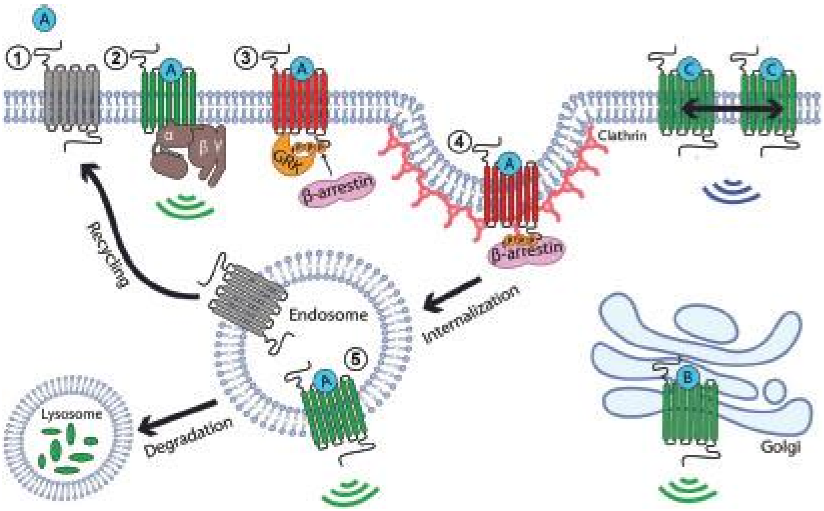

PLATE 7. ***(Figure 2-8)*** **Agonist-induced signaling and trafficking of opioid receptors.** Inactive opioid receptors (*gray*) become activated (*green*) after binding to an agonist (drug A; steps 1-2). The active receptor enables signaling via G proteins (*green ripples*, step 2) and triggers phosphorylation of the receptor tail (P) by G protein-coupled receptor kinases (GRKs), followed by receptor engagement of b-arrestins (step 3) and endocytosis via clathrin-coated pits (step 4). These events inactivate G protein signaling (*red receptor*) and ensure signal termination from the plasma membrane by endocytic removal of receptors. After receptors arrive in early endosomes, they have the capacity to signal again by engaging G proteins in the endosome membrane (*green ripples*, step 5). Receptors also engage molecular sorting mechanisms in the endosome limiting membrane (not shown), which determine whether internalized receptors are delivered to lysosomes for proteolytic downregulation or are nondestructively recycled to restore surface receptor responsiveness. Many nonpeptide agonist drugs (drug B) are sufficiently membrane-permeant to activate a discrete pool of opioid receptors at the Golgi apparatus and activate receptors from this location (*green ripples*). Some agonists (drug C) induce receptor reorganization in the plasma membrane to change surface signaling (*blue ripples*).

Source. Reprinted from Figure 1 (p. 426) in Jullie D, Gondin AB, von Zastrow M, Canals M: "Opioid Pharmacology Under the Microscope." *Molecular Pharmacology* 98:425-432, 2020 (https://doi.org/10.1124/mol.119.119321). PLATE 8. ***(Figure 2-9)*** **Models of allosteric interactions between protomers of a heteromer.**

(A) The affinity of a ligand for one protomer (*green*) can be altered by the association of the second protomer (*blue*). **(B)** Binding of an orthosteric ligand to one protomer can alter the affinity of an orthosteric ligand for the second protomer. **(C)** Binding of an orthosteric ligand to one protomer can change the signaling efficiency (intrinsic efficacy) of the orthosteric ligand for the second protomer. Shown is efficiency of coupling to a heterotrimeric G protein, but this extends to other signal-transducing molecules (e.g., b-arrestin). **(D)** Binding of an orthosteric ligand to one protomer can alter the efficiency of coupling of the receptor produced by orthosteric ligand binding to the second protomer to each of multiple transducer molecules (i.e., can alter functional selectivity or agonist bias). Shown are alterations in coupling to a G protein versus b-arrestin. **(E)** Orthosteric ligand binding to one protomer can cause a change in the G protein-coupling specificity produced by the orthosteric ligand for the second protomer (this also changes agonist bias). Shown is a change in coupling efficiency to G proteins with two different a subunits (*light vs. dark blue*).

PLATE 9. *(Figure 2-10)* Paradigms for activation of signaling proteins in response to receptor tyrosine kinase (RTK) activation.

At least two separate molecular events are required for RTK-induced activation of signaling molecules. Given that many protein targets of RTKs are located at the cell membrane, translocation of RTK to the cell membrane is essential for activation of many effector proteins. **(A) Activation of PKB (also known as Akt) by membrane translocation.** PtdIns(3,4,5)P3 generated in response to growth factor stimulation serves as a binding site for the PH domains of PDK1 and PKB. Membrane translocation is accompanied by release of an autoinhibition leading to activation of PDK1 and PKB kinase activities. Full activation of PKB requires phosphorylation by PDK1 (and also by PDK2). Activated PKB phosphorylates a variety of target proteins that prevent apoptotic death and regulate various metabolic processes. **(B) Activation by a conformational change.** Binding of the SH2 domains of p85, the regulatory subunit of PI-3 kinase, to pTyr sites on activated receptors releases an autoinhibitory constraint that stimulates the catalytic domain (p110). PI-3 kinase catalyzes the phosphorylation of the 39 positions of the inositol ring of PtdIns(4)P and PtdIns(4,5)P2 to generate PtdIns(3,4)P2 and PtdIns(3,4,5)P3, respectively. **(C) Activation by tyrosine phosphorylation.** Binding of the SH2 domains of PLCg to pTyr sites in activated receptors facilitates tyrosine phosphorylation of PLCg as well as membrane translocation, a process mediated in part by binding of the PH domain to PI-3 kinase products. Tyrosine phosphorylation is essential for PLCg activation, leading to hydrolysis of PtdIns(4,5)P2 and generation of the two second messengers Ins(1,4,5)P3 and diacyglycosol. BAD = Bcl-2 agonist of cell death; DAG = diacylglycerol; FKHR1 = winged helix transcription factor; Ins (1,4,5)P3 = inositol 1,4,5-trisphosphate; IP_3 = inositol 1,4,5-trisphosphate; p110 = catalytic subunit of PI-3 kinase; p85 = regulatory subunit of PI-3 kinase; PDK1 = pyruvate dehydrogenase kinase isoform 1; PDK2 = pyruvate dehydrogenase kinase isoform 2; PH = Pleckstrin homology; PI = phosphatidylinositol; PI-3 kinase = phosphatidylinositol-3 kinase; PIP_2 = phosphatidylinositol (4,5)-bisphosphate; PIP_3 = phosphatidylinositol (3,4,5)-trisphosphate; PKB = protein kinase B; PKC = protein kinase C; PLCg = phospholipase C gamma; PtdIns(3,4)P2 = phosphatidylinositol-bisphosphate; PtdIns(3,4,5)P3 = phosphatidylinositol (3,4,5)-trisphosphate; PtdIns(4)P = phosphatidylinositol-4-phosphate; PtdIns(4,5)P2 = phosphatidylinositol 4,5-bisphosphate; pY = phosphorylated tyrosine residue; pTyr = phosphotyrosine; SH2 = Src homology 2.

PLATE 10. ***(Figure 2-11)*** **The serotonergic system.**

(A) Location of the major serotonin (5-hydroxytryptamine [5-HT])-producing cells (raphe nuclei) innervating brain structures. **(B)** Various cellular regulatory processes involved in serotonergic neurotransmission and sites of action of drugs affecting serotonergic transmission. *L-Tryptophan*, the precursor for 5-HT, is converted to 5-hydroxytryptophan (5-HTP) by the rate-limiting enzyme tryptophan hydroxylase (TrpH). Aromatic L-amino acid decarboxylase (*AADC*) then converts 5-HTP to 5-HT. Once released from the presynaptic terminal, 5-HT can interact with a variety (14 different types) of presynaptic and postsynaptic receptors. *Sumatriptan*, a $5\text{-HT}_{1B,1D}$ receptor agonist, has antimigraine effects that are thought to be due to activation of $\text{HT}_{1B,1D}$ receptors expressed on smooth muscle (to produce vasoconstriction) and also on pain-sensing neurons (i.e., *nociceptors*) (to reduce the release of pain-related neuropeptides). *Buspirone* is a partial 5-HT_{1A} receptor agonist that activates both pre-and postsynaptic receptors. *Cisapride* is a preferential 5-HT_4 receptor agonist that is used to treat irritable bowel syndrome as well as nausea associated with antidepressants. Binding of 5-HT to G protein-coupled receptors (GPCRs) that are coupled to adenylyl cyclase (AC) and phospholipase C beta (PLCb) will result in production of a cascade of second-messenger and cellular effects. Lysergic acid diethylamide (*LSD*) likely interacts with numerous 5-HT receptors to mediate its effects. Pharmacologically, this ligand is often used as a 5-HT$_2$ receptor agonist in receptor-binding experiments. *Ondansetron* is a 5-HT$_3$ receptor antagonist that is marketed as an antiemetic agent for chemotherapy patients but is also given to counteract side effects produced by antidepressants in some patients. 5-HT has its action terminated by being taken back into the presynaptic neuron through 5-HT transporters (5-HTTs [also called SERTs]). (Note that 5-HTTs are located extrasynaptically, not synaptically [as depicted in figure].) Once inside the neuron, 5-HT can either be repackaged into vesicles for reuse or undergo enzymatic catabolism. The selective serotonin reuptake inhibitors (*SSRIs*) and older-generation tricyclic antidepressants (*TCAs*) are able to interfere with or block the reuptake of 5-HT. 5-HT is metabolized to 5-hydroxyindoleacetic acid (5-HIAA) by monoamine oxidase (MAO), located on the outer membrane of mitochondria or sequestered and stored in secretory vesicles by vesicular monoamine transporters (VMATs). *Reserpine* causes a depletion of 5-HT in vesicles by interfering with uptake and storage mechanisms (depressive-like symptoms have been reported with this agent). *Tranylcypromine* is an MAO inhibitor (MAOI) and an effective antidepressant. *Fenfluramine* (an anorectic agent) and 3,4-methylenedioxymethamphetamine (*MDMA*; "Ecstasy") are able to facilitate 5-HT release by altering SERT function. cAMP = cyclic adenosine monophosphate; DAG = diacylglycerol; IP$_3$ = inositol 1,4,5-triphosphate.

PLATE 11. ***(Figure 2-12)*** **The dopaminergic system.**

(A) Dopaminergic neurons are located in the ventral midbrain in the A9 (substantia nigra pars compacta) and A10 (ventral tegmental area) regions. DA = dopamine.**(B)** Synthesis of dopamine starts with the nonessential amino acid L-tyrosine. The rate-limiting step is conversion of L-tyrosine to L-dihydroxyphenylalanine (L-DOPA) by the enzyme tyrosine hydroxylase (TH). Aromatic L-amino acid decarboxylase (AADC) then converts L-DOPA to dopamine, which can be metabolized to 3,4-dihydroxyphenylacetic acid (DOPAC) by intraneuronal monoamine oxidase (MAO) or sequestered and stored in secretory vesicles by vesicular monoamine transporters (VMATs). Once released, dopamine acts on pre-and postsynaptic metabotropic receptors and is terminated via reuptake by perisomatic dopamine transporters (DATs). (Note that DATs are located extrasynaptically, not synaptically [as depicted in figure].) AMPT = a-methyl-*p*-tyrosine; cAMP = cyclic adenosine monophosphate; COMT = catechol-O-methyltransferase; HVA = homovanillic acid; MT = methoxytyramine. **(C)** Four separate dopamine pathways are present in the brain that play distinct roles in pathophysiology and therapeutic intervention: the mesocortical pathway (*yellow*), the nigrostriatal pathway (*blue*), the mesolimbic pathway (*red*), and the tuberoinfundibular pathway (*green*).

PLATE 12. ***(Figure 2-13)*** **The noradrenergic system**

(A) Noradrenergic neurons of the locus coeruleus are located in the pons of the brain stem. **(B)** Synthesis of norepinephrine (NE) starts with the amino acid L-tyrosine, which is actively transported into presynaptic NE nerve terminals from extracellular fluid. The rate-limiting step is conversion of L-tyrosine to L-dihydroxyphenylalanine (L-DOPA) by the enzyme tyrosine hydroxylase (TH). Aromatic L-amino acid decarboxylase (AADC) converts L-DOPA to dopamine. Dopamine is then packaged into vesicles, by vesicular monoamine transporters (VMATs), and hydroxylated by dopamine b-hydroxylase (DBH) in the presence of O_2 and ascorbate to form NE. Once released from the presynaptic terminal, NE can interact with a variety of presynaptic and postsynaptic receptors. Presynaptic regulation of NE neuron firing activity and release occurs through somatodendritic (not shown) and nerve terminal a_2 adrenoreceptors, respectively. Binding of NE to G proteins (G_o, G_i, etc.) that are coupled to adenylyl cyclase (AC) and phospholipase C beta (PLCb) produces a cascade of second-messenger and cellular effects. NE's action is terminated when it is taken back into the presynaptic neuron via NE transporters (NETs). (Note that NETs are located extrasynaptically, not synaptically [as depicted in figure].) Once inside the neuron, NE can either be repackaged into vesicles for reuse or undergo enzymatic degradation. AMPT = a-methyl-*p*-tyrosine; cAMP = cyclic adenosine monophosphate; COMT = catechol-O-methyltransferase; DA = dopamine; DAG = diacylglycerol; IP_3 = inositol 1,4,5-triphosphate; MAO = monoamine oxidase; MHPG = 3-methoxy-4-hydroxyphenylglycol; NM = normetanephrine.

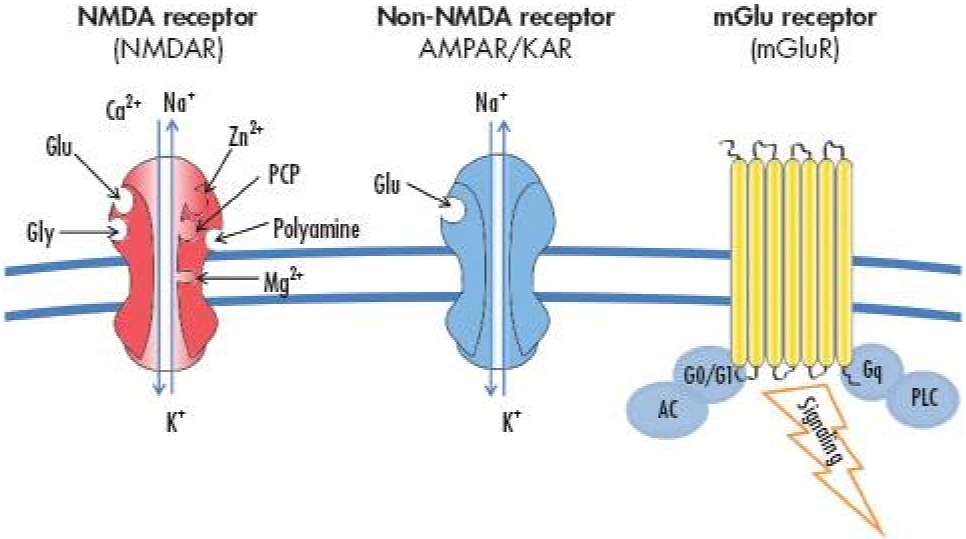

PLATE 13. ***(Figure 2-15)*** **Glutamatergic receptors.**

Ionotropic glutamate receptors mediate fast excitatory signaling in the brain; however, glutamate also plays a modulatory role through activation of metabotropic receptors. The a-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) and kainate receptors (AMPAR and KAR) are activated by glutamate and are permeable to Na^+, which results in a rapid, transient depolarization of the plasma membrane. In contrast, *N*-methyl-D-aspartate (NMDA) receptors are more complex, being blocked by Mg^{2+} at hyperpolarized membrane potentials and permeable to Ca^{2+}, permitting activation of various intracellular cascades. AC = adenylyl cyclase; G0/G1, Gq = Gi/o protein a subunits; PLC = phospholipase C; PCP = phencyclidine.

PLATE 14. ***(Figure 2-16)*** **The GABAergic system.**

GABA is synthesized from glutamate by the enzyme glutamic acid decarboxylase (GAD) and, following release, binds to both ionotropic GABA_A and metabotropic GABA_B receptors. GABA_A receptors are ligand-gated $\text{Cl}^{[?]}$ channels that hyperpolarize the cell and mediate fast inhibitory signaling in the brain. GABA_A receptors are heteropentameric receptor complexes, composed of numerous subunit isoforms that determine agonist affinity, allosteric modulation, and other channel properties. Note that GABA transporters are located both synaptically (as shown in figure) and extrasynaptically. AC = adenylyl cyclase; cAMP = cyclic adenosine monophosphate; GABA-T = GABA transaminase; GAT = GABA transporter; TBPS = *t*-butylbicyclophosphorothionate; VGAT = vesicular GABA transporter.

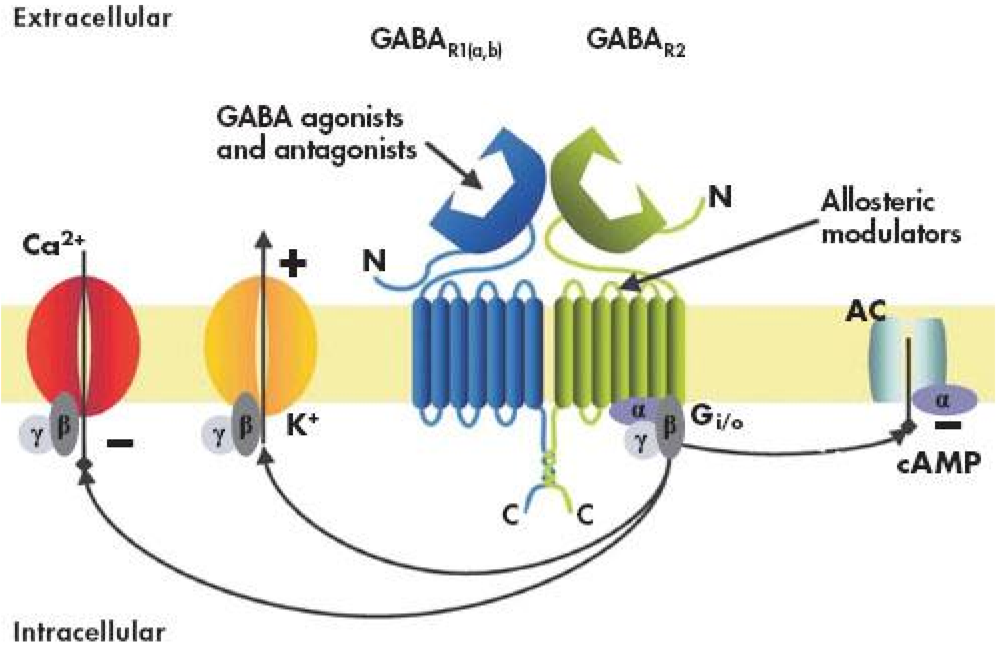

PLATE 15. ***(Figure 2-17)*** **$GABA_B$ receptors.**

The metabotropic $GABA_B$ receptors are GPCRs assembled as heterodimers from two subunits of the receptor ($GABA_{B1}$ and $GABA_{B2}$) coupled to $G_{i/o}$. Activation of $GABA_B$ receptors inhibits adenylyl cyclase, decreasing cAMP production. In addition, the Gbg subunit directly activates G protein-activated K^+ channels and inhibits voltage-gated Ca^{2+} channels, resulting in neuronal inhibition. AC = adenylyl cyclase; C = C-terminus; cAMP = cyclic adenosine monophosphate; $GABA_{R1(a,b)}$, $GABA_{R2}$ = $GABA_{B1}$ subunits; $G_{i/o}$ = Gi/o protein a subunit; N = N-terminus.

PLATE 16. ***(Figure 2-18)*** **Production, transport, and metabolism of adenosine.**

Intracellular adenosine is produced via dephosphorylation from the main source, AMP, via both cN-I and cN-II and hydrolysis of *S*-adenosyl-homocysteine through the enzyme *S*-adenosyl-L-homocysteine hydrolase. The extracellular formation of adenosine is the result of enzymatic cascades consisting of ATP transport, hydrolysis of ATP and ADP by CD39 to form AMP, and dephosphorylation of AMP by CD73. Extracellular adenosine binds adenosine receptors (A_1AR, A_{2A}AR, A_{2B}AR, and A_3AR) on the surface of cells. Each adenosine receptor is a GPCR that transmits the signal from adenosine by stimulating or inhibiting cyclic AMP (cAMP). AC = adenylyl cyclase; ADA = adenosine deaminase; ADO = adenosine; ADP = 5'-adenosine diphosphate; AMP = 5'-adenosine monophosphate; AR = adenosine receptor; ATP = 5'-adenosine triphosphate; CD = ectonucleotidase cluster of differentiation; cN = cytosolic 5'-nucleotidase; ENT = equilibrative nucleoside transporter; GMP = guanosine monophosphate; GPCR = G protein-coupled receptor; IMP = inosine monophosphate; INO = inosine.

PLATE 19. *(Figure 2-21)* Signaling bias of opioid ligands.

Opioid receptor activation of G protein signaling leading to increased ion channel activity (GIRK and Ca_V channels) and inhibition of AC was thought to mediate analgesia, whereas b-arrestin signaling was associated with adverse side effects (e.g., constipation, respiratory depression). However, more recent studies suggest that b-arrestin signaling may not underlie the development of constipation and respiratory depression, whereas G protein-mediated pathways may contribute to the development of these adverse effects. AC = adenylyl cyclase; Ca_V = voltage-gated calcium channel; GIRK = G protein-coupled inwardly rectifying potassium [channel].

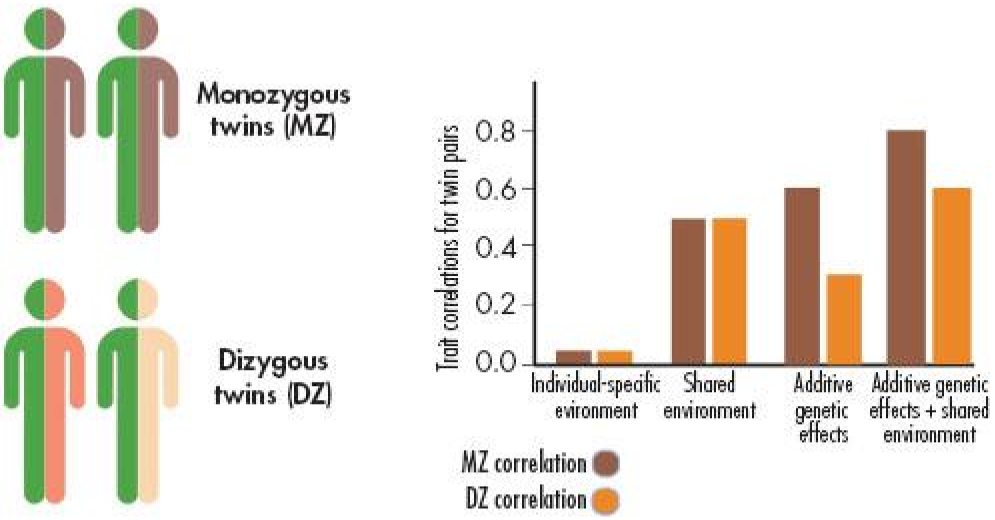

PLATE 21. ***(Figure 3-2)*** **Patterns of intrapair correlations in twins and the source of variance implied.**

Correlation of phenotypes/traits between monozygotic (MZ) and dizygotic (DZ) twin pairs illustrating different scenarios of genetic and environmental contributions to disease. Intrapair correlations of around zero imply effects of individual-specific environment. Equal intrapair correlations that are greater than zero for MZ and DZ twins imply effects of shared environment. Correlations for MZ twins that are twice as great as those for DZ twins imply additive genetic effects. Correlations for MZ twins that are greater than--but not twice as great as--those for DZ twins imply additive genetic effects and shared environment effects. Correlations of less than 1.0 are likely mediated by individual-specific environment effects.

PLATE 23. ***(Figure 3-5)*** **Epigenetic mechanisms.**

This figure summarizes the different types of epigenetic modifications. **(1)** DNA modifications: Cytosines can be modified by methylation, hydroxymethylation, formylation, and carboxylation, whereas adenines can only be modified by methylation (adenylation). **(2)** Chromatin modifications: Nucleosomes, composed of DNA wrapped around histone proteins, can change position to increase or decrease DNA accessibility. Nucleosomes also can be modified by adding histone variants and posttranslational modifications. **(3)** Noncoding RNAs can regulate transcription and thus are also considered an epigenetic mechanism. **(4)** RNA modifications (epitranscriptomics): Gene expression can be influenced by RNA modifications, which are also reversible. DNMT2 = DNA methyltransferase-like protein 2; METTL3 = methyltransferase-like 3.

PLATE 25. ***(Figure 4-1)*** **Physiology of the neuroendocrine system.**

Schematic representation of the four major neuroendrocrine elements: the hypothalamic-pituitary-adrenal (HPA), hypothalamic-pituitary-thyroid (HPT), and hypothalamic-pituitary-gonadal (HPG) axes and the hypothalamic-neurohypophyseal system (HNS). Hypothalamic neurons produce releasing hormones and HNS hormones. Releasing hormones act on the anterior pituitary gland, causing the release of stimulating hormones. HNS hormones are released from hypothalamic axons in the posterior pituitary, or neurohypophysis. The stimulating hormones produced in the pituitary gland stimulate peripheral organs (thyroid, gonads, and adrenal cortex) to produce specific hormones, which in turn exert several biological functions (T_3, T_4; testosterone, progesterone, estrogens; and cortisol, respectively). These peripheral hormones can act backwards within each axis, self-controlling their production in a negative feedback loop. The HPT axis is represented in *yellow*; the HPG in *red*; the HPA in *green*; the hypothalamus and HNS in *blue*; and the pituitary gland in *light blue*. *Arrows* indicate stimulation, and *dotted lines* indicate inhibition. Hormone-producing organs are described in *rounded boxes*, and hormonal products are depicted as *rectangles*. 49 Treatment of Bipolar Disorder

Stephen M. Strakowski, M.D.

Paul E. Keck Jr., M.D.

50 Treatment of Anxiety Disorders

Soo-Hee Choi, M.D., Ph.D.

Murray B. Stein, M.D., M.P.H., FRCPC

51 Treatment of Posttraumatic Stress Disorder

Charles B. Nemeroff, M.D., Ph.D.

Valerie Rosen, M.D.

Nicholas F. Ortiz, M.D.

52 Treatment of Obsessive-Compulsive Disorder ...

Reilly R. Kayser, M.D.
H. Blair Simpson, M.D., Ph.D.

53 Treatment of Schizophrenia
Mary F. Brunette, M.D.
Jacob S. Ballon, M.D.
Samantha A. Gnanasegaram, M.D.
Agnieszka Kalinowski, M.D., Ph.D.
William R. Keller, M.D.
Jeffrey D. Reed, D.O.
Doug L. Noordsy, M.D.
54 Treatment of Substance Use Disorders
Brian J. Sherman, Ph.D.
Karen J. Hartwell, M.D.
Aimee L. McRae-Clark, Pharm.D.
Alexandra Herron, B.A.
Kathleen T. Brady, M.D., Ph.D.
55 Treatment of Alcohol Use Disorder
Barbara J. Mason, Ph.D.
Eva Ritvo, M.D.
Antonello Bonci, M.D.
56 Treatment of Personality Disorders
Eric Hollander, M.D.
Tarini Vats, M.D.
Nilifa Desilva, M.P.H.
57 Treatment of Eating Disorders
W. Stewart Agras, M.D.
58 Treatment of Insomnia
Andrew D. Krystal, M.D., M.S.

Appendix: Properties of Agents Commonly Used to Treat Insomnia

59 Treatment of Chronic Pain

R. Garrett Key, M.D.

Kurt Kroenke, M.D.

60 Treatment of Child and Adolescent Disorders

Karen Dineen Wagner, M.D., Ph.D.

Steven R. Pliszka, M.D.

Appendix: Psychotropic Medications Commonly Prescribed for Children and Adolescents

61 Treatment During Late Life

Katharine K. Brewster, M.D.

Bret R. Rutherford, M.D.

Steven P. Roose, M.D.

62 Treatment of Women Excluding Pregnancy and Postpartum

Korrina A. Duffy, Ph.D.

Sarah Nagle-Yang, M.D.

C. Neill Epperson, M.D.

63 Psychopharmacology During Pregnancy and Lactation

D. Jeffrey Newport, M.D.

Teresa Lanza di Scalea, M.D., Ph.D.

Erin Richardson, M.S.N., R.N., A.P.R.N.

Tawny Smith, Pharm.D.

Nicole Scott, M.D.

Zachary N. Stowe, M.D.

64 Treatment of Attention-Deficit/Hyperactivity Disorder in Adults

Elizabeth Deckler, M.D.

Barbara Coffey, M.D., M.S.

65 Treatment of Individuals With Intellectual Developmental Disorder

Katharine Stratigos, M.D.

Julia Katz, M.D.

David Hong, M.D.

66 Treatment of Autism Spectrum Disorder

John P. Hegarty II, Ph.D.

Antonio Y. Hardan, M.D.

Appendix: Outcome Measures for Assessment of Core Symptom Domains in Autism Spectrum Disorder

67 Treatment of Psychiatric Emergencies

Roger L. McRoberts, M.D. Steven J. Garlow, M.D., Ph.D.

Appendix of Psychiatric Medications

Robert H. Chew, Pharm.D.

Robert B. MacArthur, Pharm.D., M.S.

Index

Contributors

Anzar Abbas, Ph.D.
CEO, Brooklyn Health, Brooklyn, New York

Elias Aboujaoude, M.D., M.A.
Clinical Professor, Department of Psychiatry and Behavioral Sciences, Stanford University School of Medicine, Stanford, California

W. Stewart Agras, M.D.
Professor of Psychiatry Emeritus, Department of Psychiatry and Behavioral Sciences, Stanford University School of Medicine, Stanford, California

Alessandra Alciati, M.D.
Researcher, Department of Clinical Neurosciences, Villa San Benedetto Menni--Hermanas Hospitalarias, Albese con Cassano (Como), Italy; Consultation-liaison psychiatrist, Humanitas Clinical and Research Center, Rozzano (Milan), Italy

Jorge Almeida, M.D., Ph.D.
Director, UT Health Austin Bipolar Disorder Center, Mulva Clinic for the Neurosciences; Associate Professor, Department of Psychiatry and Behavioral Sciences, Dell Medical School, University of Texas at Austin, Austin, Texas

Gayle Ayers, D.O.
Associate Professor, Department of Psychiatry, Texas Tech University Health Sciences Center, School of Medicine, Lubbock, Texas

Jacob S. Ballon, M.D.
Clinical Professor, Department of Psychiatry and Behavioral Sciences, Stanford University School of Medicine, Stanford, California

Kelly A. Berg, Ph.D.
Professor/Research, Department of Pharmacology, University of Texas Health Science Center at San Antonio

Elisabeth B. Binder, M.D., Ph.D.
Director, Department of Genes and Environment, Max Planck Institute of Psychiatry, Munich, Germany; Professor, Department of Psychiatry and Behavioral Sciences, Department of Human Genetics, Emory University School of Medicine, Atlanta, Georgia

Nikolajs K. Birze, M.D.
Psychiatrist, Mindpath Health, Austin, Texas

Pierre Blier, M.D., Ph.D.
Professor, Departments of Psychiatry and Cellular and Molecular Medicine, University of Ottawa, The Royal Ottawa Institute of Mental Health Research, Ottawa, Ontario, Canada

Antonello Bonci, M.D.
Founder and Executive Chairman, GIA Miami and Vita Recovery; Founder and Scientific Director, Brain & Care, Miami, Florida; former Professor, Department of Neurology, UCSF, San Francisco, California; former Scientific Director, NIDA/NIH, Baltimore, Maryland

Charles L. Bowden, M.D.[‡‡]
Fellow Emeritus, American College of Neuropsychopharmacology; Nancy U. Karren Clinical Professor, Department of Psychiatry, and Professor, Department of Pharmacology, University of Texas Health Science Center at San Antonio

Kathleen T. Brady, M.D., Ph.D.
Director, South Carolina Clinical and Translational Research Center; Distinguished University Professor, Medical University of South Carolina, Charleston, South Carolina

Katharine K. Brewster, M.D.
Assistant Professor of Psychiatry, Columbia University Vagelos College of Physicians and Surgeons, New York, New York

Frank W. Brown, M.D.
Associate Professor, Department of Psychiatry and Behavioral Sciences, Emory University School of Medicine, Decatur, Georgia

Mary F. Brunette, M.D.
Professor of Psychiatry, Professor of Community and Family Medicine, and Professor of The Dartmouth Institute of Health Policy and Practice, Geisel School of Medicine at Dartmouth, Hanover, New Hampshire

Peter F. Buckley, M.D.
Chancellor, University of Tennessee Health Science Center, and Professor, Department of Psychiatry, College of Medicine, Memphis, Tennessee

Joseph R. Calabrese, M.D.
Emeritus Professor of Psychiatry and Former Director of the Bipolar Disorder Research Center, Case Western Reserve University School of Medicine; Founder and Former Director of the Mood Disorders Program, Department of Psychiatry, University Hospitals Cleveland Medical Center, Cleveland, Ohio

Soo-Hee Choi, M.D., Ph.D.
Associate Professor, Departments of Psychiatry, Seoul National University College of Medicine, Seoul, Republic of Korea

Leslie Citrome, M.D., M.P.H.
Clinical Professor, Department of Psychiatry and Behavioral Sciences, New York Medical College, Valhalla, New York

William P. Clarke, Ph.D.
Distinguished Teaching Professor and Maharaj Ticku Professor of Pharmacology, Department of Pharmacology, University of Texas Health Science Center at San Antonio

Anita H. Clayton, M.D.
Wilford W. Spradlin Professor and Chair, Department of Psychiatry and Neurobehavioral Sciences, University of Virginia School of Medicine, Charlottesville, Virginia

Barbara Coffey, M.D., M.S.
Professor and Chair, Department of Psychiatry and Behavioral Sciences, University of Miami Miller School of Medicine, Miami, Florida

Samuel J. Collier, M.D.
Affiliate Faculty, Seton Mind Institute (Ascension Seton Medical Center and UT Health), Department of Psychiatry and Behavioral Sciences, University of Texas Dell Medical School, Austin, Texas

Jeffrey Cummings, M.D., Sc.D.(HS)
Joy Chambers-Grundy Professor of Brain Science and Director, Chambers-Grundy Center for Transformative Neuroscience, Department of Brain Health, School of Integrated Health Sciences, University of Nevada, Las Vegas, Las Vegas, Nevada

Darina Czamara, Ph.D.
Team Leader, Department of Genes and Environment, Max Planck Institute of Psychiatry, Munich, Germany

Karon Dawkins, M.D.
Associate Professor, Vice Chair of Education, and Director, General Psychiatry Residency Program, Department of Psychiatry, University of North Carolina School of Medicine, Chapel Hill, North Carolina

Lynette C. Daws, Ph.D.
Frost Bank Distinguished Professor in Biomedical Research, Departments of Cellular & Integrative Physiology and Pharmacology, University of Texas Health Science Center at San Antonio

Charles DeBattista, D.M.H., M.D.

Professor of Psychiatry and Behavioral Sciences and Director, Depression Research Clinic, Stanford University School of Medicine, Stanford, California

Elizabeth Deckler, M.D.
Child and Adolescent Psychiatry Fellow Physician, New York-Presbyterian Hospital/Weill Cornell Medical Center, Columbia University Irving Medical Center, and New York State Psychiatric Institute, New York, New York

Charles-Yoland Desfosses, M.D.
Psychiatrist, Department of Psychiatry and Neuroscience, Laval University, Pavillon Ferdinand-Vandry, Quebec, Quebec, Canada

Nilifa Desilva, M.P.H.
Senior Research Regulatory Coordinator, Centre for Addiction and Mental Health, Toronto, Ontario, Canada

Firdaus S. Dhabhar, Ph.D.
Professor, Department of Psychiatry & Behavioral Sciences, Department of Microbiology & Immunology, and the Sylvester Comprehensive Cancer Center, Miller School of Medicine, University of Miami, Miami, Florida

Korrina A. Duffy, Ph.D.
Research Scientist, Department of Psychiatry, School of Medicine, University of Colorado Anschutz Medical Campus, Aurora, Colorado

C. Neill Epperson, M.D.
Robert Freedman Endowed Chair and Professor, Department of Psychiatry, School of Medicine, University of Colorado Anschutz Medical Campus; Professor, Department of Family Medicine, School of Medicine, University of Colorado Anschutz Medical Campus; and Executive Director, Helen and Arthur E. Johnson Depression Center, University of Colorado Anschutz Medical Campus, Aurora, Colorado

David Erritzoe, M.D., Ph.D., MRCPsych
Clinical Senior Lecturer in Psychiatry, Centres for Neuropsychopharmacology and Psychedelic Research, Division of Psychiatry, Central and North West London (CNWL)-Imperial Psychopharmacology and Psychedelic Research (CIPPRes) Clinic, St. Charles Hospital, CNWL Mental Health NHS Foundation Trust, London, UK

Julie Farrington, M.D.
Assistant Professor, Department of Psychiatry & Behavioral Sciences, Dell Medical School; and Psychiatrist, Mulva Clinic for the Neurosciences, UT Health Austin, The University of Texas at Austin

Adriana E. Foster, M.D.
Professor and Vice-Chair for Clinical and Research Services, Department of Psychiatry and Behavioral Health, Herbert Wertheim College of Medicine, Florida International University, Miami, Florida

Alan Frazer, Ph.D.
Professor, Department of Pharmacology, University of Texas Health Science Center at San Antonio; Adjunct Professor of Pharmacology in Psychiatry, Department of Psychiatry, University of Pennsylvania Perelman School of Medicine, Philadelphia, Pennsylvania

Mark A. Frye, M.D.
Professor, Department of Psychiatry and Psychology, Mayo Clinic, Rochester, Minnesota

Isaac R. Galatzer-Levy, Ph.D.
Adjunct Assistant Professor, Department of Psychiatry, New York University Grossman School of Medicine; Google LLC, Mountain View, California

Keming Gao, M.D., Ph.D.
Professor of Psychiatry and Director of Bipolar Disorder Research Center, Case Western Reserve University; Director of the Mood Disorders Program, Medical Director of Electroconvulsive Therapy, and Director of Ketamine

Infusion and Repetitive Transcranial Stimulation in the Department of Psychiatry, University Hospitals Cleveland Medical Center, Cleveland, Ohio

Erica C. Garcia-Pittman, M.D., FAPA, DFAAGP
Associate Professor, Department of Psychiatry and Behavioral Sciences, Dell Medical School, The University of Texas at Austin; Outpatient Clinical Director, Ascension Medical Group Seton Behavioral Health, Austin, Texas

Steven J. Garlow, M.D., Ph.D.
Professor (Clinical Health Sciences track), Wisconsin Psychiatric Institute and Clinic, Department of Psychiatry, University of Wisconsin School of Medicine and Public Health, Madison, Wisconsin

Milena Girotti, Ph.D.
Assistant Professor/Research, Department of Pharmacology, University of Texas Health Science Center at San Antonio

Samantha A. Gnanasegaram, M.D.
Assistant Professor of Psychiatry, Geisel School of Medicine at Dartmouth, Hanover, New Hampshire

Donald C. Goff, M.D.
Director, Nathan S. Kline Institute for Psychiatric Research, Orangeburg, New York; and Marvin Stern Professor of Psychiatry and Vice Chair for Research, Department of Psychiatry, New York University Grossman School of Medicine, New York, New York

Joseph F. Goldberg, M.D.
Clinical Professor of Psychiatry, Icahn School of Medicine at Mount Sinai, New York, New York

Robert N. Golden, M.D.
Robert Turell Professor in Medical Leadership and Dean, University of Wisconsin School of Medicine and Public Health; Vice Chancellor for

Medical Affairs, University of Wisconsin-Madison, Madison, Wisconsin

Anna I. Guerdjikova, Ph.D., LISW, CCRC
Associate Clinical Professor, Department of Psychiatry and Behavioral Neuroscience, University of Cincinnati College of Medicine, Cincinnati, Ohio; Director of Administrative Services, Harold C. Schott Foundation Eating Disorders Program, Lindner Center of HOPE, Mason, Ohio

Salvador Guinjoan, M.D. Ph.D.
Principal Investigator, Laureate Institute for Brain Research, Tulsa, Oklahoma

David V. Hamilton, M.D., M.A.
Psychiatrist, Charlottesville, Virginia

Antonio Y. Hardan, M.D.
Professor, Department of Psychiatry and Behavioral Sciences, Stanford University, Stanford, California

Karen J. Hartwell, M.D.
Professor, Medical University of South Carolina, Charleston, South Carolina

Philip D. Harvey, Ph.D.
Leonard M. Miller Professor, Department of Psychiatry and Behavioral Sciences; Director, Division of Psychology; and Vice Chair for Research, University of Miami Miller School of Medicine, Miami, Florida

John P. Hegarty II, Ph.D.
Clinical Assistant Professor, Department of Psychiatry and Behavioral Sciences, Stanford University, Stanford, California

Alexandra Herron, B.A.
Research Assistant in Addiction Sciences, Medical University of South Carolina, Charleston, South Carolina

Michele Hill, MRCPsych
Consultant Psychiatrist, CATCH service, South Lee Health Service Executive, Cork University Hospital, Cork, Ireland

Robert M. A. Hirschfeld, M.D.[++]
Fellow Emeritus, American College of Neuropsychopharmacology; DeWitt Wallace Senior Scholar and Professor of Psychiatry, Weill Cornell Medical College, New York, NewYork

Eric Hollander, M.D.
Professor, Department of Psychiatry and Behavioral Sciences, Albert Einstein College of Medicine/Montefiore Medical Center, Bronx, New York

David Hong, M.D.
Associate Professor, Department of Psychiatry and Behavioral Sciences, Stanford University School of Medicine, Stanford, California

Jonathon R. Howlett, M.D.
Assistant Professor, Department of Psychiatry, University of California San Diego, La Jolla; and Staff Psychiatrist, VA San Diego Healthcare System, San Diego, California

Dawn F. Ionescu, M.D.
Senior Director and Clinical Leader, Neuroscience Experimental Medicine, Janssen Pharmaceuticals, La Jolla, California

Manish K. Jha, M.D.
Assistant Professor and O'Donnell Clinical Neuroscience Scholar, Department of Psychiatry, University of Texas Southwestern Medical Center, Dallas, Texas

Agnieszka Kalinowski, M.D., Ph.D.
Instructor (Affiliate), Department of Psychiatry and Behavioral Sciences, Stanford University School of Medicine, Stanford, California; Staff Physician, Veterans Administration Palo Alto Health Care, Palo Alto, California

Julia Katz, M.D.
Attending Psychiatrist, Section of Neurodevelopmental Disorders, Department of Child and Adolescent Psychiatry and Behavioral Sciences, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

Reilly R. Kayser, M.D.
Assistant Professor, Department of Psychiatry, Columbia University, New York, New York

Paul E. Keck Jr., M.D.
Psychiatrist in Chief and Founding President and CEO Emeritus, Lindner Center of HOPE, University of Cincinnati Health, Mason, Ohio; and Craig and Frances Lindner Professor of Psychiatry and Behavioral Neuroscience, University of Cincinnati College of Medicine, Cincinnati, Ohio

William R. Keller, M.D.
Assistant Professor of Psychiatry, Geisel School of Medicine at Dartmouth, Hanover, New Hampshire

Terence A. Ketter, M.D.
Professor Emeritus, Department of Psychiatry and Behavioral Sciences, Stanford University School of Medicine, Stanford, California

Jessica Keverne, Ph.D.
Max Planck Institute of Psychiatry, Munich, Germany

R. Garrett Key, M.D.
Assistant Professor of Psychiatry, University of Texas at Austin Dell Medical School, Austin, Texas

Lorrin M. Koran, M.D.
Professor (Clinical) of Psychiatry and Behavioral Sciences, Emeritus Active, Stanford University School of Medicine, Stanford, California

K. Ranga Rama Krishnan, M.D.

Professor Emeritus of Psychiatry and Behavioral Sciences, Behavioral Medicine & Neurosciences Division, Duke University School of Medicine, Durham, North Carolina; Senior Advisor to the CEO, RUSH University System for Health and RUSH University Medical Center, Chicago, Illinois

Kurt Kroenke, M.D.
Professor of Medicine, Indiana University School of Medicine, Regenstrief Institute, Indianapolis, Indiana

Holly Krohn, M.P.H.
Research Instructor, Department of Psychiatry, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina

Andrew D. Krystal, M.D., M.S.
Ray and Dagmar Dolby Distinguished Professor, Departments of Psychiatry and Neurology; Vice-Chair for Research in Psychiatry; Director, USCF Dolby Family Center for Mood Disorders; Director, UCSF Interventional Psychiatry Program; and Director, Clinical and Translational Sleep Research Program, University of California San Francisco, California

Teresa Lanza di Scalea, M.D., Ph.D.
Affiliate Faculty, Departments of Psychiatry and Behavioral Sciences and of Women's Health, University of Texas at Austin Dell Medical School, Austin, Texas

Jared Lipsey, B.Sc.
Licensing Associate, MIT Technology Licensing Office, Cambridge, Massachusetts

Daniel J. Lodge, Ph.D.
Professor and Chair, Joe R. and Teresa Lozano Long Endowed Chair of Pharmacology, Department of Pharmacology and Center for Biomedical Neuroscience, University of Texas Health Science Center at San Antonio; Research Scientist, South Texas Veterans Health Care System, Audie L. Murphy Division, San Antonio, Texas

Leonardo V. Lopez, M.D.
Associate Professor of Clinical Psychiatry, Department of Psychiatry, Weill Cornell Medical College, New York, New York

Robert B. MacArthur, Pharm.D., M.S.
Director of Pharmacy Services, Rockefeller University Hospital, New York, New York

Stephen R. Marder, M.D.
Professor and Department Vice Chair, Psychiatry and Biobehavioral Sciences; Director, Section on Psychosis, Semel Institute for Neuroscience & Human Behavior, David Geffen School of Medicine, University of California Los Angeles; Director, VISN-22 Mental Illness Research Education and Clinical Center, Veterans Health Administration Greater Los Angeles Healthcare System, Los Angeles, California

Laura Marsh, M.D.
Executive Director, Mental Health Care Line, Michael E. DeBakey Veterans Affairs Medical Center; Professor, Departments of Psychiatry and Neurology, and Program Director, Behavioral Neurology & Neuropsychiatry Fellowship, Department of Psychiatry and Behavioral Sciences, Baylor College of Medicine, Houston, Texas

Barbara J. Mason, Ph.D.
Pearson Family Professor and Director, Pearson Center for Alcoholism and Addiction Research, The Scripps Research Institute, La Jolla, California

David S. Mathai, M.D.
Postdoctoral Researcher and Assistant Faculty, Department of Psychiatry and Behavioral Sciences, Johns Hopkins Medicine, Baltimore, Maryland

Sanjay J. Mathew, M.D.
Professor and Marjorie Bintliff Johnson and Raleigh White Johnson Jr. Chair for Research in Psychiatry, Menninger Department of Psychiatry and Behavioral Sciences, Baylor College of Medicine, Houston, Texas

Taryn L. Mayes, M.S.

Program Manager, Center for Depression Research and Clinical Care, Peter O'Donnell Jr. Brain Institute and Department of Psychiatry, University of Texas Southwestern Medical Center, Dallas, Texas

W. Vaughn McCall, M.D., M.S.
Professor and Case Distinguished University Chair, Department of Psychiatry and Health Behavior, Medical College of Georgia, Augusta University, Augusta, Georgia

William M. McDonald, M.D.
J. B. Fuqua Chair for Late-Life Depression and Reunette W. Harris Chair for Psychiatry and Behavioral Sciences, Emory University School of Medicine, Atlanta, Georgia

Susan L. McElroy, M.D.
Chief Research Officer and Consultant to Eating Disorders Team, Lindner Center of HOPE, Mason, Ohio; Professor, Department of Psychiatry and Behavioral Neuroscience, University of Cincinnati College of Medicine, Cincinnati, Ohio

Aimee L. McRae-Clark, Pharm.D.
Professor, Medical University of South Carolina, Charleston, South Carolina

Roger L. McRoberts, M.D.
Assistant Professor, Department of Psychiatry & Behavioral Sciences, University of Texas at Austin Dell Medical School, Austin, Texas

Thomas W. Meeks, M.D.
Assistant Professor of Psychiatry, Oregon Health & Science University, Vancouver, Washington

Samantha Meltzer-Brody, M.D., M.P.H.
Assad Meymandi Distinguished Professor and Chair; Director, Center for Women's Mood Disorders, Department of Psychiatry, University of North

Carolina at Chapel Hill, Chapel Hill, North Carolina

Emmanuel Mignot, M.D., Ph.D.
Craig Reynolds Professor of Sleep Medicine and Professor of Psychiatry and Behavioral Sciences, Stanford University School of Medicine, Palo Alto, California; Director, Stanford Center for Sleep Sciences and Medicine, Palo Alto, California

Andrew H. Miller, M.D.
William P. Timmie Professor of Psychiatry and Behavioral Sciences; Director, Behavioral Immunology Program; and Vice Chair, Research, Department of Psychiatry and Behavioral Sciences, Emory University School of Medicine, Atlanta, Georgia

Katherine Marshall Moore, M.D.
Assistant Professor, Department of Psychiatry and Psychology, Mayo Clinic, Rochester, Minnesota

Sarah Nagle-Yang, M.D.
Associate Professor, Department of Psychiatry, and Medical Director, Women's Behavioral Health and Wellness Service, School of Medicine, University of Colorado Anschutz Medical Campus, Aurora, Colorado

Henry A. Nasrallah, M.D.
Professor Emeritus, Department of Psychiatry and Behavioral Neuroscience, University of Cincinnati College of Medicine, Cincinnati, Ohio

J. Craig Nelson, M.D.
Professor of Psychiatry, Leon J. Epstein Endowed Chair in Geriatric Psychiatry, and Director of Geriatric Psychiatry Fellowship Program, Department of Psychiatry, University of California-San Francisco, San Francisco, California

Charles B. Nemeroff, M.D., Ph.D.
Matthew P. Nemeroff Endowed Chair and Professor, Department of Psychiatry and Behavioral Sciences, Mulva Clinic for the Neurosciences;

Director, Institute of Early Life Adversity Research, Dell Medical School, University of Texas at Austin

John W. Newcomer, M.D.
President and CEO, Thriving Mind South Florida, Miami, Florida; Adjunct Professor of Psychiatry, Washington University School of Medicine, St. Louis, Missouri

D. Jeffrey Newport, M.D.
Professor, Departments of Psychiatry and Behavioral Sciences and of Women's Health, University of Texas at Austin Dell Medical School, Austin, Texas

Linda Nicholas, M.D.
Professor of Psychiatry (retired), University of North Carolina School of Medicine, Chapel Hill, North Carolina

Naoya Nishino, M.D.
Visiting Postdoctoral Scholar, Department of Psychiatry and Behavioral Sciences, Sleep and Circadian Neurobiology Laboratory, Stanford University School of Medicine, Palo Alto, California

Seiji Nishino, M.D., Ph.D.
Professor of Psychiatry and Behavioral Sciences, Stanford University School of Medicine, Stanford, California; Director, Sleep and Circadian Neurobiology Laboratory, Stanford Sleep Research Center, Palo Alto, California

Doug L. Noordsy, M.D.
Clinical Professor, Department of Psychiatry & Behavioral Sciences, Stanford University School of Medicine, Stanford, California

Julio C. Nunes, M.D.
Psychiatry Resident, Department of Psychiatry, Yale University School of Medicine, New Haven, Connecticut

David Nutt, FRCP, FRCPsych, FBPhS, FMedSci, D.Laws.
Professor of Neuropsychopharmacology, Centres for Neuropsychopharmacology and Psychedelic Research, Division of Psychiatry, Imperial College London, London, UK

Taisuke Ono, M.D., Ph.D.
Postdoctoral Scholar, Department of Psychiatry and Behavioral Sciences, Sleep and Circadian Neurobiology Laboratory, Stanford University School of Medicine, Palo Alto, California

Nicholas F. Ortiz, M.D.
Assistant Professor, Department of Psychiatry and Behavioral Sciences, Dell Medical School, The University of Texas at Austin

Carmine Maria Pariante, M.D., Ph.D., FRCPsych
Department of Psychological Medicine, Institute of Psychiatry, Psychology and Neuroscience, King's College London; National Institute for Health and Research Biomedical Research Centre at South London and Maudsley NHS Foundation Trust and King's College London, London, United Kingdom

Riah Patterson, M.D.
Assistant Professor, Department of Psychiatry, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina

Martin P. Paulus, M.D.
Scientific Director and President, Laureate Institute for Brain Research, Tulsa, Oklahoma

Giampaolo Perna, M.D., Ph.D.
Professor of Psychiatry & Academic Mental Health Area Coordinator, Department of Biological Sciences, Humanitas University, Pieve Emanuele (Milan), Italy; Chair, Department of Clinical Neurosciences, Villa San Benedetto Menni--Hermanas Hospitalarias, Albese con Cassano (Como), Italy

Steven R. Pliszka, M.D.
Dielmann Distinguished Professor and Chair, Department of Psychiatry and Behavioral Sciences, University of Texas Health Science Center at San Antonio, Texas

Robert M. Post, M.D.
Head, International Bipolar Collaborative Network, Bethesda, Maryland; Clinical Professor, Department of Psychiatry and Behavioral Sciences, The George Washington University School of Medicine and Health Sciences, Washington, DC

Charles L. Raison, M.D.
Mary Sue and Mike Shannon Distinguished Chair for Healthy Minds, Children & Families; Professor, School of Human Ecology; and Professor, Department of Psychiatry, School of Medicine and Public Health, University of Wisconsin-Madison, Madison, Wisconsin

Mark M. Rasenick, Ph.D.
Distinguished UIC Professor, Departments of Physiology & Biophysics and Psychiatry, University of Illinois at Chicago College of Medicine, Chicago, Illinois; Career Research Scientist, Jesse Brown VA Medical Center, Chicago, Illinois

Jeffrey D. Reed, D.O.
Assistant Professor of Psychiatry, Geisel School of Medicine at Dartmouth, Hanover, New Hampshire

Erin Richardson, M.S.N., R.N., A.P.R.N.
Health Professional Specialist, Department of Psychiatry and Behavioral Sciences, University of Texas at Austin Dell Medical School, Austin, Texas

Karl Rickels, M.D.
Emeritus Professor of Psychiatry, Department of Psychiatry, University of Pennsylvania Perelman School of Medicine, Philadelphia, Pennsylvania

Eva Ritvo, M.D.

Private practice; former Chair, Department of Behavioral Medicine, Mount Sinai Medical Center, Miami Beach, Florida; former Vice Chair, Department of Psychiatry and Behavioral Sciences, University of Miami Miller School of Medicine, Miami, Florida

Donald S. Robinson, M.D.[++]
Consultant, Worldwide Drug Development, Shelburne, Vermont

Francisco Romo-Nava, M.D., Ph.D.
Research Associate Professor, Department of Psychiatry and Behavioral Neuroscience, University of Cincinnati College of Medicine, Cincinnati, Ohio; Associate Chief Research Officer, Lindner Center of HOPE, Mason, Ohio

Steven P. Roose, M.D.
Professor of Clinical Psychiatry, Columbia University Vagelos College of Physicians and Surgeons, New York, New York

Valerie Rosen, M.D.
Associate Professor, Department of Psychiatry and Behavioral Sciences, Dell Medical School, The University of Texas at Austin

Jerrold F. Rosenbaum, M.D.
Stanley Cobb Professor of Psychiatry, Department of Psychiatry, Harvard Medical School; Psychiatrist-in-Chief Emeritus and Director of Center for Anxiety and Traumatic Stress Disorders and of Center for Neuroscience of Psychedelics, Massachusetts General Hospital, Boston, Massachusetts

Bret R. Rutherford, M.D.
John and Myrna Daniels Associate Professor of Psychiatry in Honor of Dr. Herbert Pardes, Columbia University Vagelos College of Physicians and Surgeons, New York, New York

Noriaki Sakai, D.V.M., Ph.D.

Basic Life Research Scientist, Department of Psychiatry and Behavioral Sciences, Sleep and Circadian Neurobiology Laboratory, Stanford University School of Medicine, Palo Alto, California

Khalid Salaheldin, M.D.
Clinical Assistant Professor, Department of Psychiatry and Behavioral Sciences, Stanford University School of Medicine, Stanford, California

Alan F. Schatzberg, M.D.
Kenneth T. Norris Jr. Professor, Department of Psychiatry and Behavioral Sciences, Stanford University School of Medicine, Stanford, California; Director, Stanford Mood Disorders Center

Nicole Scott, M.D.
Perinatal Psychiatrist, Reproductive Psychiatry Clinic of Austin, Texas

Luca Sforzini, M.D.
Department of Psychological Medicine, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom

David V. Sheehan, M.D., M.B.A., DLFAPA, FACPsych
Distinguished University Health Professor Emeritus, University of South Florida Morsani College of Medicine, Tampa, Florida

Richard C. Shelton, M.D.
Charles Byron Ireland Professor, Department of Psychiatry and Behavioral Neurobiology, Heersink School of Medicine, The University of Alabama at Birmingham

Brian J. Sherman, Ph.D.
Assistant Professor, Medical University of South Carolina, Charleston, South Carolina

H. Blair Simpson, M.D., Ph.D.

Professor and Director, Center for OCD and Related Disorders, Department of Psychiatry, Columbia University/New York State Psychiatric Institute, New York, New York

Tawny Smith, Pharm.D.
Associate Professor, Departments of Psychiatry and Behavioral Sciences and Women's Health, University of Texas at Austin Dell Medical School, Austin, Texas

David Spelber, M.D.
Psychiatrist, Austin, Texas

Murray B. Stein, M.D., M.P.H., FRCPC
Distinguished Professor, Departments of Psychiatry and of Family Medicine and Public Health, University of California San Diego, La Jolla; and Psychiatry Service, Veterans Affairs San Diego Healthcare System, San Diego, California

Keri A. Stevenson, M.D.
Assistant Professor, Department of Psychiatry and Behavioral Medicine, Virginia Tech Carilion School of Medicine, Roanoke, Virginia

Zachary N. Stowe, M.D.
Professor of Psychiatry, University of Wisconsin School of Medicine and Public Health, Madison, Wisconsin

Stephen M. Strakowski, M.D.
Professor and Vice Chair, Research of Psychiatry, Indiana University School of Medicine, Indianapolis, Indiana; and Associate Vice President for Regional Mental Health and Professor, Departments of Psychiatry & Behavioral Sciences, Psychology, and Educational Psychology, Dell Medical School, University of Texas at Austin

Martin T. Strassnig, M.D.
Adjunct Associate Professor of Psychiatry, Department of Psychiatry, University of Miami Miller School of Medicine, Miami, Florida

Katharine Stratigos, M.D.
Assistant Clinical Professor of Psychiatry, Columbia University Department of Psychiatry (Voluntary Faculty), and Medical Director, NYSTART Triborough Region 4, New York, New York

Rajiv Tandon, M.D.
Professor Emeritus, Department of Psychiatry, Western Michigan University Homer Stryker M.D. School of Medicine, Kalamazoo, Michigan

Michael E. Thase, M.D.
Professor of Psychiatry, Perelman School of Medicine, University of Pennsylvania, Corporal Michael J. Crescenz Veterans Affairs Medical Center, Philadelphia, Pennsylvania

Madhukar H. Trivedi, M.D.
Professor of Psychiatry; Chief, Division of Mood Disorders; and Director, Center for Depression Research and Clinical Care, Peter O'Donnell Jr. Brain Institute and Department of Psychiatry, University of Texas Southwestern Medical Center, Dallas, Texas

Tarini Vats, M.D.
Research Fellow, Albert Einstein College of Medicine, Bronx, New York

Karen Dineen Wagner, M.D., Ph.D.
Titus Harris Chair and Professor, Department of Psychiatry and Behavioral Sciences, University of Texas at Galveston, Texas

Claes Wahlestedt, M.D., Ph.D.
Professor and Director, Center for Therapeutic Innovation, Department of Psychiatry and Behavioral Sciences, University of Miami Miller School of Medicine, Florida

Po W. Wang, M.D.
Clinical Professor, Department of Psychiatry and Behavioral Sciences, Stanford University School of Medicine, Stanford, California

Frances Isabella Weston, B.Sc.
Department of Psychological Medicine, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom

Yvonne S. Yang, M.D., Ph.D.
Health Sciences Assistant Clinical Professor, Department of Psychiatry and Biobehavioral Sciences, David Geffen School of Medicine, University of California Los Angeles; Director, Psychiatry Residency Research Program, UCLA Semel institute for Neuroscience and Human Behavior; Director, Thoughts and Perceptions Clinic, and Section Chief, Psychosis Section, Greater Los Angeles Veterans Affairs Healthcare System; Los Angeles, California

Jiang-Zhou Yu, M.D., Ph.D.
Research Assistant Professor, Departments of Physiology & Biophysics and Surgery, University of Illinois at Chicago College of Medicine, Chicago, Illinois

Chloe J. Yuan, M.D.
Psychiatrist, Texas Child Study Center, Austin, Texas

Zane Zeier, Ph.D.
Associate Professor, Department of Psychiatry and Behavioral Sciences, University of Miami Miller School of Medicine, Miami, Florida

Charles F. Zorumski, M.D.
Samuel B. Guze Professor of Psychiatry and Neuroscience, Washington University School of Medicine, St. Louis, Missouri

Disclosure of Interests

The following contributors have indicated a financial interest in or other affiliation with a commercial supporter, manufacturer of a commercial product, and/or provider of a commercial service, as listed below:

Anzar Abbas, Ph.D. *Employment:* Cambridge Cognition; *Stock Holdings:* AiCure LLC.

Alessandra Alciati, M.D. *Consultant:* Eli Lilly, Janssen, Menarini.

Jacob S. Ballon, M.D. *Scientific Advisory Board:* Alkermes; *Consultant:* Alto Pharmacy; *Research Support:* Alkermes, Corcept, Roche.

Pierre Blier, M.D., Ph.D. *Advisory Board/Speaking Honoraria/Consultant:* Allergan, Janssen, Lundbeck/Otsuka, Merck, Pfizer; *Grant/Research Support:* Allergan, Janssen, Ontario Brain Institute/Canadian Institutes of Health Research.

Antonello Bonci, M.D. *Company Ownership:* GIA Miami (for-profit) and Brain&Care (startup) offer patient services including transcranial magnetic stimulation (TMS).

Kathleen T. Brady, M.D., Ph.D. *Consultant:* Sage Pharmaceuticals, Alkermes Pharmaceuticals, and Genomind.

Leslie Citrome, M.D., M.P.H. *Consultant:* AbbVie/Allergan, Acadia, Alkermes, Angelini Pharma, Astellas, Axsome, BioXcel, Boehringer Ingelheim, Cadent Therapeutics, and Cerevel; *Speaking Honoraria:* AbbVie/Allergan, Acadia, Alkermes, Angelini Pharma, Axsome, BioXcel, Eisai, Idorsia, Intra-Cellular Therapies, Janssen, Lundbeck, Neurocrine Biosciences, Noven, Otsuka, Recordati, Sage, Sunovion, and Teva, and CME activities organized by medical education companies such as Medscape, North American Center for Continuing Medical Education (NACCME), Neuroscience Education Institute (NEI), and Vindico Medical Education, as well as universities and professional organizations/societies; *Publication/Writing Honoraria:* Taylor & Francis (Editor-in-Chief, *Current Medical Research and Opinion*, 2022-present), UpToDate (reviewer), and Elsevier (Topic Editor, Psychiatry, *Clinical Therapeutics*).

Anita H. Clayton, M.D. *Consultant:* S1 Biopharma and Takeda/Lundbeck; *Stock:* S1 Biopharma.

Barbara Coffey, M.D., M.S. *Honoraria:* American Academy of Child and Adolescent Psychiatry, Harvard Medical School Psychiatry Academy, National Institute of Mental Health (NIMH), Teva/Nuvelution Pharma; *Grant/Research Support:* Emalex Biosciences, Florida Children's Medical Services, Partners Healthcare; *Medical/Scientific Advisory Board:* Skyland Trail, Teva/Nuvelution, Tourette Association of America (TAA-CDC Partnership).

Jeffrey Cummings, M.D., Sc.D. *Consultant:* Acadia, Alkahest, AriBio, Avanir, Axsome, Behren Therapeutics, Biogen, Cassava, Cerecin, Cerevel, Cortexyme, Diadem, EIP Pharma, Eisai, GemVax, Genentech, Green Valley, Grifols, Janssen, Merck, Novo Nordisk, Oligomerix, Otsuka, PRODEO, reMYND, Renew, Resverlogix Corp, Roche, Signant Health, Suven, United Neuroscience, Unlearn AI; *Copyright Holder:* Neuropsychiatric Inventory (NPI); *Grant/Research Support:* National Institute of General Medical Sciences (NIGMS) grant P20GM109025; National Institute on Neurological Disorders and Stroke (NINDS) grant U01NS093334; National Institute on Aging (NIA) grants R01AG053798, P20AG068053, and R35AG71476.

Charles DeBattista, D.M.H., M.D. *Research Support:* Compass, Beckley Scitech, Relmada, Magnus, Sage; *Advisory Boards:* AbbVie, Corcept.

C. Neill Epperson, M.D. *Consultant/Advisor:* Asarina Pharma, Sage Therapeutics; *Grant/Research Support:* Sage Therapeutics; *Scientific Advisory Board:* Babyscripts.

David Erritzoe, M.D., Ph.D., MRCPsych *Consultant:* Aya Biomedical, Clerkenwell Health, and Mindstate Design Labs; *Speaking Honoraria:* Compass Pathways.

Julie Farrington, M.D. *Grants:* Cancer Prevention Institute of Texas (CPRIT) grant for tobacco cessation study (co-investigator); National Institutes of Health (NIH) R01 grant for Re-EMBARC open-label study of sertraline (co-investigator); *Expert Testimony:* Thornton, Biechlin, Reynolds & Guerra (law firm); *Travel/Meeting Support:* Anxiety and Depression Association of America (ADAA) 2023 Conference; *Advisory Board:* Chair, Behavioral Health Subcommittee of Ascension Texas Hospital Network Clinical Care Council (unpaid); *Grant/Research Support:* Boehringer Ingelheim, Compass Pathways, Jazz, LivaNova PLC, Navidea Biopharmaceuticals, and Sage Therapeutics.

Mark A. Frye, M.D. *Grant/Research Support:* Assurex Health; *Speaking Honoraria:* American Physician Institute, Carnot Laboratories; *Royalties:*

Chymia LLC; *Scientific Steering Committee:* Breakthrough Discoveries for Thriving with Bipolar Disorder (BD^2).

Isaac R. Galatzer-Levy, Ph.D. *Employment/Stock Holdings:* Facebook LLC.

Joseph F. Goldberg, M.D. *Consultant:* Alkermes, Intra-Cellular Therapies, Neumora, Neurelis, Otsuka, Takeda, and Sunovion; *Speaking Honoraria:* Alkermes, Axsome, and AbbVie; *Royalties:* American Psychiatric Association Publishing and Cambridge University Press.

Anna I. Guerdjikova, Ph.D., LISW, CCRC *Consultant:* Axsome Therapeutics and Signant Health.

Antonio Y. Hardan, M.D. *Consultant:* Beaming Health, Finch Therapeutics, IAMA Therapeutics, and Jazz Pharmaceuticals.

Philip D. Harvey, Ph.D. *Consultant:* Alkermes, Boehringer Ingelheim, Karuna Pharma, Merck Pharma, Minerva Neurosciences, and Sunovion; *Grant/Research Support:* Alkermes; *Stock:* i-Function; *Royalties:* VeraSci/WCG Clinical Endpoints.

Eric Hollander, M.D. *Editorial Honoraria:* Elsevier (Editor-in-Chief, *Journal of Psychiatric Research*); *Grant/Research Support:* Abbott, U.S. Department of Defense (DoD), GW Pharma, U.S. FDA Office of Orphan Products Development (OOPD), and Roche.

David Hong, M.D. *Grant/Research Support:* NIH, Teleo Inc; *Stock:* Little Otter Inc.

Dawn F. Ionescu, M.D. *Employment:* Johnson & Johnson / Janssen Pharmaceuticals.

Manish K. Jha, M.D. *Grant/Research Support:* Janssen Research & Development, Navitor/Supernus, and Neurocrine Bioscience; *Editorial Honoraria:* Psychiatry & Behavioral Health Learning Network (Section Editor); Elsevier (Guest Editor, *Psychiatric Clinics of North America*); *Consultant:* Boehringer Ingelheim, Eleusis/Beckley Psytech, Guidepoint Global, Janssen Global Services, and Janssen Scientific Affairs; *Data Safety and Monitoring Board:* IQVIA (Click), Vicore Pharma, and Worldwide Clinical Trials (Eliem, Inversargo); *Honoraria:* Clinical Care Options, Global Medical Education, Medscape/WebMD, North American Center for Continuing Medical Education, and H. C. Wainwright & Co.

Agnieszka Kalinowski, M.D., Ph.D. *Consultant:* Pasithea Therapeutics.

Paul E. Keck Jr., M.D. *Consultant:* Biohaven; *Speaking Honoraria:* Alkermes, Axsome, Otsuka-Lundbeck, and Teva; *Royalties:* UpToDate.

Terence A. Ketter, M.D. *Grant/Research Support:* Agency for Healthcare Research and Quality, Merck & Co., and Sunovion Pharmaceuticals; *Consulting Fees:* AbbVie, Alkermes, Allergan Pharmaceuticals, Otsuka Pharmaceuticals, and Sunovion Pharmaceuticals; *Speaking Honoraria/Advisory Board/Royalties:* Acadia Pharmaceuticals, Allergan Pharmaceuticals, American Psychiatric Publishing Inc., GlaxoSmithKline, Janssen Pharmaceuticals, Myriad Genetic Laboratories, Navigen, Otsuka Pharmaceuticals, Sunovion Pharmaceuticals, Supernus Pharmaceuticals, and Teva Pharmaceuticals.

K. Ranga Rama Krishnan, M.D. *Consultant:* Sage Therapeutics; *Royalties:* Atai; *Officer/Director/Trustee:* AmyriAD Therapeutics.

Holly Krohn, M.P.H. *Grant/Research Support:* Sage Therapeutics.

Andrew D. Krystal, M.D., M.S. *Grant/Research Support:* Attune, Axsome Pharmaceutics, Harmony Biosciences, Janssen Pharmaceuticals, NIH, Neurocrine Biosciences, The Ray and Dagmar Dolby Family Fund, and Reveal Biosensors; *Consultant/Speaking Honoraria:* Adare Pharma, Angelini Pharma, Axsome Therapeutics, Big Health, Eisai, Evecxia Therapeutics, Ferring Pharmaceuticals, Galderma, Harmony, Idorsia, Janssen, Jazz, Millennium Pharmaceuticals, Merck, Neurocrine, NeuraWell Therapeutics, Otsuka, Pernix Therapeutics, Sage, and Takeda; *Stock:* Big Health and NeuraWell Therapeutics.

Teresa Lanza di Scalea, M.D., Ph.D. Owner of Women's Psychiatry and Well-Being PLLC, private practice (09/2022-present).

Daniel J. Lodge, Ph.D. *Consultant:* Alkermes; *Grant/Research Support:* Heptares Therapeutics.

Stephen R. Marder, M.D. *Consultant:* Boehringer Ingelheim, Karuna Therapeutics, Merck, and Sunovion; *Grant/Research Support:* Boehringer Ingelheim.

Barbara J. Mason, Ph.D. *Consultant:* Imbrium Therapeutics; *Scientific Advisory Board:* Awakn Life Sciences and Imbrium Therapeutics; *Grant/Research Support:* National Institute on Alcohol Abuse and

Alcoholism (NIAAA) grants P60AA006420, P60AA006420, R21AA023821, and U01AA025476; *Stock:* Awakn Life Sciences.

Sanjay J. Mathew, M.D. *Consultant:* Almatica Pharma, Biohaven, Boehringer Ingelheim, Clexio Biosciences, Engrail Therapeutics, Neumora, Perception Neurosciences, and Relmada Therapeutics.

William V. McCall, M.D., M.S. *Consultant:* Carelon and Idorsia; *Honoraria/Nonroyalty Payment (for scale development):* Wolters Kluwer.

Susan L. McElroy, M.D. *Consultant:* Idorsia, Levo, Novo Nordisk, Otsuka, Sunovion, and Takeda; *Grant/Research Support:* Axsome, Marriott Foundation, Novo Nordisk, Otsuka, and Sunovion.

Samantha Meltzer-Brody, M.D., M.P.H. *Grant/Research Support* (to UNC): Sage Therapeutics; *Consultant:* EmbarkNeuro, Modern Health (professional corporation).

Andrew H. Miller, M.D. *Consultant:* Boehringer Ingelheim, Cerevel Therapeutics, and Sirtsei Pharmaceuticals.

Henry A. Nasrallah, M.D. *Consultant:* Acadia, Boehringer Ingelheim, Cerevel, and Karuna; *Speaking Honoraria:* AbbVie, Alkermes, Indivior, Intra-Cellular Therapies, Janssen, Neurocrine, Otsuka, and Teva.

J. Craig Nelson, M.D. *Research Support:* NIMH; *Consultant:* Biohaven, Johnson & Johnson, Novartis, and Otsuka; *Royalties:* UpToDate.

Charles B. Nemeroff, M.D., Ph.D. *Consultant:* ANeuroTech, BioXcel Therapeutics, Clexio Biosciences, EmbarkNeuro, Engrail Therapeutics, GoodCap Pharmaceuticals, Heading Health LLC, Intra-Cellular Therapies (ITI), Multidisciplinary Association for Psychedelic Studies (MAPS) Public Benefit Corp., Ninnion Therapeutics, Pasithea Therapeutics, PreciseMent Health, Relmada Therapeutics, Sage Therapeutics, Senseye, Signant Health, Silo Pharma, and SynapseBio.

John W. Newcomer, M.D. *Consultant:* Biohaven, Bristol Myers Squibb, Merck, Optum, and Sunovion; *Data Safety Monitoring Committee:* Amgen and Teva.

D. Jeffrey Newport, M.D. *Consultant:* Janssen, Merck, and Sage Therapeutics; *Grant/Research Support:* Navitor Pharmaceuticals, Sage Therapeutics, and Takeda.

David Nutt, FRCP, FRCPsych, FBPhS, FMedSci, D.Laws. *Shares/Advisory Fees:* Awakn Life Sciences, Neural Therapeutics, and

Psyched Wellness; *Consultant:* Algernon Pharmaceuticals and Compass Pathways; *Speaking Honoraria:* Lundbeck, Otsuka, and Takeda.

Carmine Maria Pariante, M.D., Ph.D. Prof. Pariante is supported by the Wellcome Trust strategy award to the Neuroimmunology of Mood Disorders and Alzheimer's Disease (NIMA) Consortium (104025), which is also funded by Janssen, GlaxoSmithKline, Lundbeck, and Pfizer; by National Alliance for Research on Schizophrenia and Depression (NARSAD) grant RE14032; by the U.K. Medical Research Council (MR/N015746/1); and by the National Institute for Health Research Biomedical Research Centre at South London and Maudsley National Health Service Foundation Trust and King's College London. Prof. Pariante has received research and consultancy funding from pharmaceutical companies interested in the development of novel strategies for depression, such as Johnson & Johnson, Lundbeck, and Boehringer Ingelheim. Prof. Pariante has received research funding from the Innovative Medicines Initiative 2 Joint Undertaking under grant agreement No 853966-2, as part of the EU-PEARL project. This Joint Undertaking receives support from the European Union's Horizon 2020 research and innovation programme and European Federation of Pharmaceutical Industries and Associations (EFPIA).

Martin P. Paulus, M.D. *Consultant:* Hoffmann-La Roche; *Royalties:* UpToDate; *Officer/Director/Trustee:* Spring Care Inc.

Giampaolo Perna, M.D., Ph.D. *Consultant:* Lundbeck, Medibio Ltd, A. Menarini Industrie Farmaceutiche Riunite Srl, and Pfizer.

Steven R. Pliszka, M.D. *Grant/Research Support:* Otsuka.

Robert M. Post, M.D. *Speaking Honoraria:* AbbVie and Sunovion.

Charles L. Raison, M.D. *Consultant:* Emory Healthcare, Novartis, Sage/Biogen, and Usona Institute.

Mark M. Rasenick, Ph.D. *Stock, Patents, Officer/Director/Trustee:* Pax Neuroscience.

Francisco Romo-Nava, M.D., Ph.D. *Consultant:* Otsuka; *Grant/Research Support:* Brain & Behavior Research Foundation (BBRF; formerly

NARSAD), NIMH (K23MH120503), and Soterix Medical; *Patent:* USPTO Patent #10,857,356.

Jerrold F. Rosenbaum, M.D. *Officer/Director/Trustee:* Cerebral Inc, Entheos Labs, Psy Therapeutics, and Sensorium Therapeutics.

Alan F. Schatzberg, M.D. *Consultant:* Alto Neuroscience, ANeuroTech, Bracket, Delpor, Galen, Magnus, McKinsey, NeuraWell, Parexel, and Sage; *Stock/Equity:* Alto Neuroscience, ANeuroTech, Corcept (co-founder), Delpor, Madrigal, Magnus, Merck, NeuraWell, Owl Insights, Seattle Genetics, Titan, and Xhale.

Luca Sforzini, M.D.Dr. Sforzini has received research funding from the Innovative Medicines Initiative 2 Joint Undertaking under grant agreement No 853966-2, as part of the EU-PEARL project. This Joint Undertaking receives support from the European Union's Horizon 2020 research and innovation programme and EFPIA.

Richard C. Shelton, M.D. *Consultant:* Boehringer Ingelheim, Janssen, Neurocrine Biosciences, Novartis International AG, Otsuka, Seelos, and Sumitomo; *Grant/Research Support:* Alto Neuroscience, Alto Pharmaceuticals, Denovo Biopharma, INmune Bio, Intra-Cellular Therapies, Janssen, LivaNova PLC, Navitor Pharmaceuticals, Neumora, and Neurocrine.

H. Blair Simpson, M.D., Ph.D. *Employment (Stipend):* American Medical Association (Associate Editor, *JAMA Psychiatry*); *Royalties:* UpToDate.

Murray B. Stein, M.D., M.P.H. *Consultant:* Acadia Pharmaceuticals, Aptinyx, atai Life Sciences, Big Health, Bionomics, BioXcel Therapeutics, Boehringer Ingelheim, Clexio, Eisai, EmpowerPharm, Engrail Therapeutics, Janssen, Jazz Pharmaceuticals, NeuroTrauma Sciences, PureTech Health, Roche/Genentech, and Sumitomo Pharma. *Stock:* EpiVario and Oxeia Biopharmaceuticals. *Editorial Honoraria:* Wiley (Editor-in-Chief, *Depression and Anxiety*), Elsevier (Deputy Editor, *Biological Psychiatry*), and Wolters Kluwer (Co-Editor-in-Chief for Psychiatry, UpToDate). *Grant/Research Support:* NIH, U.S. Department of Veterans Affairs, and DoD. *Scientific Advisory Board:* ADAA and BBRF.

Zachary N. Stowe, M.D. *Grant/Research Support:* NIH and CDC; *Study Section Remuneration:* NIH/National Institute of Child Health and Human Development (NICHD); *Consultant:* Harvard/Brigham promotion committee.

Stephen M. Strakowski, M.D. *Employment:* Editor, *Journal of Mood and Anxiety Disorders* (ADAA); *Consultant:* Meadow Mental Health Policy Institute, Oxford University Press, and Sunovion; *Royalties:* Oxford University Press.

Madhukar H. Trivedi, M.D. *Consultant:* Alto Neuroscience, Axsome Therapeutics, Biogen MA, Cerebral Inc, Circular Genomics, Compass Pathfinder, Daiichi Sankyo, GH Research Ltd, Heading Health, Janssen, Legion Health, Merck Sharp & Dohme Corp, Mind Medicine (MindMed), Naki Health Ltd, Neurocrine Biosciences, Otsuka American Pharmaceutical, Otsuka Pharmaceutical Development & Commercialization, Praxis Precision Medicines, Relmada Therapeutics, Sage Therapeutics, Signant Health, Sparian Biosciences, Takeda Pharmaceuticals, and WebMD.

Karen Dineen Wagner, M.D., Ph.D. *Grant/Research Support:* NIAAA and State of Texas; *Employment:* Physicians Postgraduate Press (Deputy Editor, *Journal of Clinical Psychiatry*).

Po W. Wang, M.D. *Consultant:* Genentech; *Research Support:* Merck Sharp & Dohme Corp.

Charles F. Zorumski, M.D. *Scientific Advisory Board:* Sage Therapeutics; *Stock:* Sage Therapeutics; *Patents:* Neurosteroids and oxysterols as modulators of glutamate and GABA receptors; Redox modulation of T-type calcium channels; Ent-neurosteroids and glaucoma. *Speaking Honoraria:* CME Outfitters.

Introduction

In 1996, we published the first edition of the *Textbook of Psychopharmacology*, which was generally acknowledged as an immediate success, and we are delighted that the sixth edition of *The American Psychiatric Association Publishing Textbook of Psychopharmacology* is now being published. The field has grown greatly in the past 25-plus years, with amazing advances in neuroscience, psychopharmacology, and brain stimulation therapies. Commensurate with this growth, we have with each edition tried to present the most salient information both from basic neuroscience as it relates to the pathogenesis and pathophysiology underlying psychiatric disorders and from basic and clinical psychopharmacology. Each successive edition has understandably become larger as we have attempted to keep pace with the ever-growing body of knowledge in the field. The *Textbook* now has more than 160 authors--including more than 75 new contributors. It has 12 all-new chapters, and it is fully aligned with the revised DSM-5-TR classification. This Sixth Edition is published in two volumes.

The opening section in Volume 1--Principles of Neuropsychopharmacology--contains 9 chapters and provides a tour of the multiple disciplines that undergird the chapters to come, with topics extending from the principles of molecular biology and genomics to the rudiments of neuroimaging and personalized medicine in psychiatry. The second section--Classes of Psychiatric Treatments--contains 38 chapters and provides a comprehensive examination of the medication classes used in psychopharmacological treatment as well as the available neuromodulation therapies. For each drug within a class, data are reviewed on history and discovery, preclinical and clinical pharmacology, pharmacokinetic parameters, mechanism of action, indications and efficacy, side effects and toxicology, and drug-drug interactions. Similar data are provided for brain stimulation modalities. A detailed Index closes this volume.

Volume 2 of the *Textbook* contains the third and final section--Psychopharmacological Treatment--and consists of 20 chapters focused on psychopharmacological approaches to treatment of patients with major psychiatric disorders (e.g., mood and anxiety disorders, schizophrenia, substance use disorders) as well as patients in specific populations (e.g., adults with ADHD, pediatric patients). For each specific condition, patient population, or setting, chapters provide guidance on topics such as medication selection, combination and maintenance dosing regimens, side-effect monitoring and management, and optimization of treatment response. Following these chapters is an Appendix of Psychiatric Medications, with key information on each of the agents covered in the *Textbook*, presented in a convenient tabular format. A detailed Index closes this volume.

Noteworthy additions to this *Textbook* include chapters addressing the following topics:

- Potential roles of personalized medicine in psychiatry and of artificial intelligence and machine learning in psychopharmacology
- New medications with novel pharmacological mechanisms, including ketamine and esketamine, the neurosteroid antidepressant brexanolone, and the atypical antipsychotic pimavanserin
- Use of investigational agents, such as psychedelics, in psychiatric treatment
- Treatment of alcohol use disorder, PTSD, OCD, and autism spectrum disorder
- Treatment of ADHD in adults
- Treatment of women in all life phases, including during pregnancy and the postpartum period
- Treatment of individuals with intellectual developmental disorder

With a level of detail not found in any other source, our new edition of *The American Psychiatric Association Publishing Textbook of Psychopharmacology* illuminates the path to effective evidence-based practice of psychopharmacology for novice and seasoned clinicians alike. We hope you will share our great enthusiasm for this Sixth Edition of the *Textbook of Psychopharmacology*.

This *Textbook* would not have been possible without the superb work of our managing editors, Adrienne Bronfeld and Kelly Puzdrak, who coordinated the efforts and time lines of the chapter authors. In addition, we wish to thank John McDuffie, who recently retired from his position as Publisher of American Psychiatric Association Publishing, for his support of this and previous editions. Greg Kuny, Managing Editor for Books, who also retired recently, has been steadfast in his editing and handling of the details of manuscript preparation. We are fortunate that his successor, Jennifer Gilbreath, has taken on this role for the Sixth Edition *Textbook*. We also are appreciative of the efforts of Rebecca Richters (Senior Editor, Books), Tammy Cordova (Senior Graphic Design Manager), Judy Castagna (Assistant Director of Production Services), and Erika Parker (Acquisitions Editor), Annie Birge (Acquisitions Coordinator), Christie Couture (Associate Director, Marketing), and Margaret May (Marketing Associate) on this and other textbooks we have edited. Robert B. MacArthur, Pharm.D., has provided superb editorial assistance in ensuring accurate information regarding formulations and dosages of all available medications. Finally, Saul Levin, Medical Director of the American Psychiatric Association, and Laura Roberts, Editor-in-Chief, have our eternal gratitude for their support on this project.

Alan F. Schatzberg, M.D.
Charles B. Nemeroff, M.D., Ph.D.

PART III

Psychopharmacological Treatment

CHAPTER 48

Treatment of Depression

Samuel J. Collier, M.D.

Charles B. Nemeroff, M.D., Ph.D.

Major depressive disorder (MDD) is a common and debilitating illness that affects people across the world. DSM-5 defines MDD as the co-occurrence of five or more defined symptoms for 2 weeks or more, including "depressed mood" or "loss of interest or pleasure," that confer substantial impairment in functioning indicative of a distinct change from a person's nondepressed functional status (American Psychiatric Association 2013). Disruptions in sleep (insomnia or hypersomnia), appetite (anorexia or hyperphagia), energy level (fatigue), and cognition (impaired concentration, indecisiveness) are common. Negative cognitions including feelings of worthlessness or guilt are also common and sometimes associated with suicidal ideation and behavior, a worrisome complication.

For 2021, the National Institute of Mental Health (NIMH) reported an annual MDD prevalence of 8.3% for adults in the United States, with women being more often affected (10.3%) than men (6.2%). The 18-to 25-year-old age group appears to be particularly vulnerable, with the highest MDD subgroup prevalence of 18.6%. Among U.S. adults experiencing a major depressive episode (MDE) with severe impairment, an estimated 74.8% received treatment (National Institute of Mental Health 2023). In line with reported prevalence values, the economic burden of MDD is astounding, with annual U.S. estimates exceeding $200 billion and a calculated annual incremental health care cost of $6,400 beyond the cost for people without MDD (Greenberg *et al.* 2015).

The goal of treatment in MDD is to achieve full remission, defined as minimal or complete absence of depressive symptoms, with full restoration of psychosocial function. This goal is driven largely by epidemiological observations, namely that residual depressive symptoms are a risk factor for relapse and recurrence of MDD, and chronicity of depressive symptoms increases the likelihood of treatment resistance (Kornstein and Schneider 2001). In essence, incomplete MDD treatment predicts a protracted illness course for the patient and a higher burden on society.

4

Epidemiology

Prevalence

MDD is one of several depressive disorders affecting people across the world. The 2017 NIMH-funded National Survey on Drug Use and Health reported that "an estimated 14.5 million U.S. adults aged 18 or older had at least one major depressive episode with severe impairment. This number represented 5.7% of all U.S. adults" (National Institute of Mental Health 2023). This staggering prevalence estimate for severe depression places MDD among the most common illnesses affecting adults across the world and includes "an estimated 5 million adolescents aged 12 to 17 in the United States" who "had at least one major depressive episode." The annual prevalence estimate of an MDE in female adolescents towered over that of male adolescents, at 29.2% versus 11.5%, with only 40.6% of all U.S. adolescents receiving treatment (National Institute of Mental Health 2023).

Persistent depressive disorder (PDD), formerly known as dysthymic disorder, is a related depressive disorder involving milder symptoms and a more chronic course compared with MDD. DSM-5 (American Psychiatric Association 2013) grouped dysthymia with other forms of chronic depression into the more expansive category of PDD as a distinction from episodic, recurrent major depressive disorder (Schramm *et al.* 2020).

Unfortunately, patients with PDD may have as much functional impairment as those with MDD and tend to have a more refractory course compared with those with nonchronic depression. PDD commonly co-occurs with MDD in a phenomenon clinically known as double depression. The National Comorbidity Survey Replication estimated the annual prevalence of PDD (2001-2003) at 1.5% of all U.S. adults, with 49.7% of these individuals having severe impairment (Kessler *et al.* 2005).

Of note, problematic diagnostic limitations continue to plague the field as lack of validated biomarkers and reliance on narrative interviewing complicate diagnostic precision and reliability. The fact that two patients with MDD can exhibit highly divergent symptom profiles, illness courses, and degrees of disability contributes to the idea that MDD is likely a phenotypic endpoint of a genetically heterogeneous illness group with differential treatment response. This idea is supported by genome-wide association studies of MDD that identity more than 40 discrete genetic loci and more than 100 genetic variants, each of which represents a small risk factor (Gerring *et al.* 2019; Howard *et al.* 2019).

Risk Factors

There are multiple risk factors for MDD, including sex, genetic loading, age, childhood maltreatment, and other environmental factors and comorbid medical illnesses. In the prepubertal phase there is no meaningful sex difference in the prevalence of MDD, but the onset of puberty marks an approximately twofold increased risk for girls compared with boys, a consequence of hormonal changes from the reproductive cycle (Kessler *et al.* 1994). This risk elevation is sustained for most of the life cycle, with intersex MDD risk eventually returning to comparable rates after age 65 years (Bebbington *et al.* 2003). Curiously, sex does not appear to influence the rates of illness recurrence in MDD.

Genetic loading plays a key part in MDD transmission, with the average general heritability risk estimated at approximately 37% (Sullivan *et al.* 2000). Some evidence suggests even greater familial risk with early-onset and recurrent MDD subtypes (Klein *et al.* 2002; Weissman *et al.* 1984).

Age is also relevant to MDD risk. Prevalence rates are generally low until early adolescence, where there is a rapid escalation that softens as patients approach middle adulthood (Wilson *et al.* 2014). After a single MDE, longitudinal epidemiological studies reveal that approximately 50% of affected people will have a second episode (and likely more thereafter), typically within 5 years of the index episode. On average, affected people experience five discrete lifetime episodes (Wilson *et al.* 2014). Lastly, patients with early-onset MDD are more likely to experience a recurrent illness course throughout life, with incomplete interepisodic recovery, briefer asymptomatic periods, higher rates of relapse and recurrence, and more chronic episodes.

Despite substantial genetic risk, nongenetic factors explain ~ 60%-70% of the variance in MDD susceptibility. This risk is determined largely by the experience of childhood adversity and other stressors, including childhood sexual abuse, general trauma, limited social support, marital strain, and divorce (Kendler *et al.* 2002, 2006). Because these problems are not modifiable with psychotropic medication, the value of psychosocial treatment cannot be overstated.

As a final point, co-occurring medical conditions are a final contributor to MDD risk, likely via a combination of direct and indirect pathophysiological mechanisms. Prior research has established an association between MDD and coronary artery disease, congestive heart failure, myocardial infarction, stroke, diabetes, cancer, autoimmune diseases, Parkinson's disease, and dementia (Iosifescu *et al.* 2003). Based on this body of literature, it is clear that comorbid medical illness, especially in multiple organ systems, correlates with lower recovery rates, greater chronicity, and worse acute phase treatment outcomes. Furthermore, there is likely a bidirectional relationship between MDD and other medical illnesses whereby depression can be a cause or consequence of medical comorbidity (Ramasubbu *et al.* 2012).

Neurobiology of Depression

As mentioned previously, there is no known single etiological driver for MDD; rather, it is best viewed as a final common pathway of various pathophysiological mechanisms that each confer risk. That said, multiple distinct biological derangements are consistently observed in MDD.

Monoamine Deficiency Hypothesis

One of the longest-standing theories of depression pathophysiology is the monoamine deficiency hypothesis. This argues that a relative depletion of serotonin, norepinephrine, or dopamine in the CNS drives depressive pathology. In support of this theory, most pharmacological compounds that increase monoamine neurotransmission have demonstrated antidepressant efficacy (Belmaker and Agam 2008). Such compounds include selective serotonin reuptake inhibitors (SSRIs), serotonin-norepinephrine reuptake inhibitors (SNRIs), tricyclic antidepressants (TCAs), heterocyclic antidepressants, monoamine oxidase inhibitors (MAOIs), and others. However, antidepressant monotherapy remission rates are generally 30% or less depending on the level of treatment resistance; thus, other factors apart from monoamine deficiency are likely at play.

Among other relevant factors, alterations in stress hormone response, elevated proinflammatory cytokines, structural and functional brain abnormalities, circadian rhythm dysfunction, neurotrophic factors, and altered glutamate and GABA neurotransmission have all been implicated as risk factors in MDD (Hasler 2010).

Neuroendocrine Dysfunction and Stress Hormones

Corticotropin-releasing hormone is released by the hypothalamus in response to psychological stress. This induces subsequent pituitary secretion of adrenocorticotropin, which then stimulates the adrenal gland to release cortisol, a major stress hormone. Women generally show higher stress responsiveness than men, consistent with the greater MDD prevalence in women (Young 1998). Although psychological stress is considered a risk factor for MDD, the majority of depressed patients do not demonstrate significant hypothalamic-pituitary-adrenal (HPA) axis dysfunction (Belmaker and Agam 2008). Regardless, nonsuppression in the dexamethasone/corticotropin-releasing hormone test is a consistent indicator of elevated relapse risk for patients with MDD during clinical remission (Schule 2007). Curiously, among patients with MDD who demonstrate alterations in stress hormone secretion, childhood trauma appears to be more prominent (Heim *et al.* 2008). The more recent finding that epigenetic regulation of glucocorticoid receptors is associated with childhood abuse establishes one link between early life adversity and HPA axis dysfunction that increases MDD risk (McGowan *et al.* 2009). Chronic elevations in cortisol may also act as a mediator between MDD and various comorbid medical conditions including coronary artery disease and type 2 diabetes mellitus, further complicating the plight of depressed patients (Gold and Chrousos 1999).

Inflammation

Proinflammatory cytokines such as interleukin-1a, tumor necrosis factor-a, and interleukin-6 also increase MDD risk by activating the HPA axis and disrupting the central serotonin system (Dantzer *et al.* 2008). Cytokine release also produces "sickness behavior" with symptoms similar to neurovegetative signs in depression, such as fatigue, anhedonia, psychomotor retardation, and cognitive impairment (Hasler 2010). Interest in the depressogenic mechanism of inflammatory cytokines stems from clinical observations of patients receiving interferon for various medical conditions (e.g., hepatitis C virus) who ultimately developed depressive symptoms. The prevalence of depression in the context of exposure to recombinant interferon is estimated to be about 30% (Loftis and Hauser 2004). Although significant, the risk is not absolute, again supporting the theory that alignment of multiple risk factors is necessary for the phenotypic expression of an MDE. Finally, some clinical data suggest that inflammatory cytokines play a more significant role in certain subsets of patients with depression--in particular, those with comorbid medical conditions (Dantzer *et al.* 2008).

Genetics and Epigenetics

Scientific inquiry about genetic risk for MDD includes family, twin, and adoption studies. Conclusions from these studies consistently find MDD to be a familial disorder with genetic factors accounting for 30%-40% of the overall risk (Sullivan *et al.* 2000). Despite high confidence from these epidemiological studies about genetic risk in MDD, there is no single candidate gene responsible for this genetic risk burden. Genome-wide association studies of MDD have identified more than 40 relevant genetic loci with more than 100 independent genetic variants, each contributing slightly to overall risk (Gerring *et al.* 2019; Howard *et al.* 2019). Nongenetic factors account for the remainder of the risk, with childhood adversity, acute or chronic interpersonal challenges, lifetime trauma, limited or absent social support, marital strain, and divorce all having substantial negative impact (Kendler *et al.* 2002 [in women]; Kendler *et al.* 2006 [in men]). The negative impact of childhood adversity on MDD expression has been more recently explained by epigenetics, that is, the alteration of gene expression by processes that do not alter the underlying genetic code. Epigenetic changes include modification in gene expression via DNA methylation and acetylation, and evidence suggests that these processes may contribute to intergenerational transmission of trauma (Lippard and Nemeroff 2020). With such a substantial proportion of MDD risk being environmentally mediated, epigenetically or otherwise, there exists significant opportunity for prevention via psychosocial interventions because psychotherapy tends to have a broader, more generalized effect compared with pharmacotherapy.

Treatment Options

Pharmacotherapies

Antidepressants are an important therapeutic option in the holistic treatment of MDD. Whereas individual antidepressant agents and their associated pharmacological profiles are addressed elsewhere in this text (see Chapters 10 through 24), this chapter reviews practical considerations in the selection and optimization of treatment and the assessment of antidepressant response while also covering nonpharmacological treatments for MDD and other depressive disorders.

Choosing the Initial Antidepressant

The 2016 Canadian Network for Mood and Anxiety Treatments (CANMAT) Clinical Guidelines for the Management of Adults with Major Depressive Disorder recommend second-generation antidepressants (SSRIs, SNRIs, mirtazapine, bupropion, vortioxetine, agomelatine) as appropriate first-line treatment interventions for MDEs of moderate or greater severity (Kennedy *et al.* 2016). Ideally, severity is determined by the degree of functional impairment caused by the neurovegetative symptom burden as measured by a validated depression rating scale, either self-or clinician-administered. For mild depressive episodes, the 2016 CANMAT MDD Guidelines recommend "psychoeducation, self-management, and psychological treatments" (Kennedy *et al.* 2016, p. 541); therefore, pharmacotherapy for MDD is typically reserved for MDEs of moderate or greater severity.

A large systematic review and network meta-analysis evaluating efficacy and acceptability of 21 first-and second-generation antidepressants found all were superior to placebo, with limited comparative efficacy differences (Cipriani *et al.* 2018). Therefore,

initial antidepressant selection for medication-naive patients is based largely on the anticipated side-effect profile. SSRIs are typically favored in this context because of superior tolerability profiles compared with SNRIs, TCAs, and MAOIs, along with relative safety, even in the context of overdose (Anderson 2000; Barbey and Roose 1998; Nemeroff *et al.* 2008). SSRI exposure (along with most other serotonergic antidepressants) does involve a well-known risk of sexual dysfunction, which can be intolerable to some patients and precipitate discontinuation. Identifying the true incidence of SSRI-mediated sexual dysfunction is complicated by the presence of preexisting depression-mediated sexual dysfunction (Montejo *et* *al.* 2018). Two European cross-sectional studies evaluating the prevalence of SSRI or SNRI sexual dysfunction reported 27%-65% of female and 26%-57% of male patients experienced either new-onset sexual dysfunction or worsening of preexisting symptoms (Williams *et al.* 2006, 2010). Luckily, there are antidepressant alternatives with minimal risk of sexual dysfunction. One meta-analysis found rates of treatment-emergent sexual dysfunction from bupropion, mirtazapine, and nefazodone to be no higher than those of placebo (Serretti and Chiesa 2009). These agents may be preferable for some patients.

Numerous other factors are relevant to antidepressant selection, of which a full discussion exceeds the scope of this chapter. Ideally, a decision is reached after a thoughtful conversation between the clinician and patient that includes a review of diagnosis, illness education, review of past treatment history and response, medical considerations (comorbidities, drug-drug interactions), risks versus benefits of various antidepressant options in the current context, patient preference, and other ancillary factors. Table 48-1 lists important considerations relevant to antidepressant selection (Kennedy *et al.* 2016).

TABLE 48-1. Factors to consider in selecting an antidepressant

Patient factors	Medication factors
* Clinical features and dimensions	* Comparative efficacy
* Comorbid conditions	* Comparative tolerability (potential side effects)
* Response and side effects during previous use of antidepressants	* Potential interactions with other medications
* Patient preference	* Simplicity of use

Of note, despite the relatively comparable efficacy of antidepressants for MDD as a whole, several major depressive subtypes warrant consideration of unique therapeutic approaches. For example, MDD with psychotic features (MDE plus delusions or hallucinations) is unlikely to respond to antidepressant monotherapy; rather, the combination of an antidepressant plus antipsychotic medication, or a course of electroconvulsive therapy (ECT), is superior (Charney and Nelson 19981). MDD with atypical features ("atypical depression"), characterized by extreme mood reactivity, rejection sensitivity, hyperphagia, hypersomnia, and leaden limb paralysis, responds more robustly to oral irreversible MAOIs than to TCAs (Henkel *et al.* 2006). MDD with seasonal pattern, known formerly as seasonal affective disorder, may benefit from routine antidepressant therapy or bright light therapy (BLT) during the fall and winter, with early morning BLT increasing the chance of remission (Maruani and Geoffroy 2019). Lastly, PDD, a DSM-5 diagnosis capturing multiple chronic depressive phenotypes, may require longer periods of treatment, with medication or psychotherapy, proportional to the degree of chronicity (Schramm *et al.* 2020). A network meta-analysis of pharmacology for PDD showed SSRIs, moclobemide, imipramine, ritanserin, and amisulpride to be more efficacious than placebo, with only fluoxetine proving less efficacious (Kriston *et al.* 2014).

Assessing and Optimizing Treatment Response

The goal of MDD treatment is to achieve full symptomatic remission with resolution of depression-mediated functional disability. This goal is important because chronic depression, defined as incomplete remission between MDD episodes or persistent symptoms for 2 or more years, increases the likelihood of treatment resistance and correlates with more severe functional impairment, more frequent suicide attempts, and worse prognosis (Kornstein and Schneider 2001). Once a patient achieves remission, the clinical focus shifts to prevention of recurrent episodes because MDD and other depressive disorders are well known to recur over the life cycle, with most patients experiencing multiple lifetime episodes (Hollon *et al.* 2002).

After selecting the initial antidepressant, the clinician should confirm the mean dosage correlating with efficacy in established clinical outcome trials and set expectations for titration to that target dosage. Lower starting dosages are commonly initiated to facilitate tolerability, but remaining at a subtherapeutic dosage may not be sufficient to evaluate benefit and risk, extending the time spent ill. For this reason, patient education about antidepressant trial adequacy is key, this being defined as exposure to a minimum effective antidepressant dosage for an adequate duration of time. An adequate antidepressant trial is generally considered to be 6-8 weeks at or above an established mean effective dosage. Inadequate antidepressant trials play a key role in negative outcomes and increased health care costs (Weilburg *et al.* 2003).

In the setting of an adequate antidepressant trial, the clinician should maintain awareness of four possible outcomes: nonresponse (0%-25% improved), partial response (25%-50% improved), response (> 50% improvement), and remission (full functional recovery). These outcomes are best defined via the combination of a clinical interview and use of a validated depression symptom severity rating instrument, either self-administered or clinician administered. Depending on the outcome of the antidepressant trial, the clinician will respond as is appropriate.

In the case of nonresponse to an initial antidepressant trial, the clinician must first rule out causal factors of pseudoresistance. Pseudoresistance, as the name implies, is the perception of treatment resistance in the setting of inaccurate diagnosis, trial inadequacy, or unrecognized treatment-interfering comorbidity (medical or psychiatric), including substance abuse (Kornstein and Schneider 2001). Table 48-2 summarizes various reasons for poor response to antidepressant therapy (Cleare *et al.* 2015; Culpepper *et al.* 2015). If pseudoresistance is ruled out, it is most prudent to switch to another antidepressant, either within the same class (e.g., SSRI to alternative SSRI) or in a different class (e.g., SSRI to SNRI). Various studies have attempted to clarify whether out-of-class switch strategies are superior to within-class switches. For example, a 2008 meta-analysis of four clinical trials (1,496 pooled subjects) revealed a small statistical advantage for depressed SSRI nonresponders who switched to a non-SSRI (bupropion, mirtazapine, venlafaxine) versus a second SSRI (28% remission vs. 23.5%) (Papakostas *et al.* 2008). In this study, the number needed to treat (NNT) was calculated at 22, meaning 22 SSRI nonresponders would have to be switched to a non-SSRI to obtain one additional remitter, a slight advantage at best.

TABLE 48-2. Reasons for poor response to antidepressant pharmacotherapy

Poor adherence to medication (consider therapeutic drug monitoring, where appropriate)
Inadequate dosage (or serum value in the case of selected TCAs)
Inadequate duration of treatment
Inaccurate diagnosis (e.g., secondary depression, bipolar I or II depression)
Undiagnosed psychiatric symptoms (e.g., psychotic or atypical features) or comorbidity (e.g., substance use disorder, personality disorder, anxiety disorder)
New or worsening medical comorbidities

Note. TCAs = tricyclic antidepressants.
Source. Cleare *et al.* 2015; Culpepper *et al.* 2015.

Drug-drug interactions (particularly concomitant medications that may worsen depressive symptoms, aggravate antidepressant side effects, or lead to excessively rapid metabolism of the antidepressant)

Undiagnosed psychosocial factors that are prolonging depressive symptoms

Note. TCAs = tricyclic antidepressants.
Source. Cleare *et al.* 2015; Culpepper *et al.* 2015.

Should a patient respond, either partially or fully, to an adequate antidepressant trial, it is important to continue to push for remission because of the elevated relapse rates and higher risk for persistent residual functional impairment in partially improved depressed patients (Culpepper *et al.* 2015). There are various treatment maneuvers to consider in this context, including antidepressant dosage optimization, adjunctive therapy (i.e., adding another medication or psychotherapy), or switching. Stepwise dosage optimization is typically preferred in the setting of good antidepressant tolerance and clear incremental benefit from prior dosage increases. Adding psychotherapy is preferred in the setting of medication intolerance, patience preference, or scenarios in which depressive symptoms are difficult to distinguish from a patient's response to psychosocial stressors. Adjunctive pharmacotherapy involves adding a second drug, either a second antidepressant (referred to as *combination therapy*) or a non-antidepressant such as an atypical antipsychotic or lithium (referred to as *augmentation therapy*).

Adjunctive therapy with a second antidepressant typically involves selecting a second agent with a different mechanism of action. Historically, clinicians have theorized that combining medications that increase central monoamine availability (i.e., serotonin, norepinephrine, dopamine) via differential mechanisms might be superior to single monoamine modulators such as SSRIs. However, efficacy data are lacking in this regard. A trial by Stewart *et al.* (2014) compared initial treatments for MDD by randomly assigning 255 subjects either to escitalopram or bupropion monotherapy or to combination escitalopram/bupropion, with no reported advantage for any treatment group at 12 weeks. A similar study by Rush *et al.* (2011) compared escitalopram monotherapy and combination therapy with either escitalopram/bupropion or venlafaxine/mirtazapine for 665 patients with moderate to severe MDD. Response and remission rates did not differ at either 12-week or 7-month endpoints; however, tolerability was worse for both combination therapy groups. Overall, the evidence supporting antidepressant combination therapy remains weak, and this approach clearly cannot be recommended at treatment initiation (Kennedy *et al.* 2016). A practical role for combination antidepressant therapy may exist in certain clinical scenarios in which a second antidepressant with a novel mechanism of action is added to improve isolated target symptoms in addition to mood (e.g., bupropion augmentation for fatigue, mirtazapine for insomnia).

Adjunctive therapy with atypical antipsychotics has a stronger evidence base than combination antidepressant therapy. A systematic review by Spielmans *et al.* (2013) examined 14 short-term trials of aripiprazole, olanzapine/fluoxetine combination (OFC), quetiapine, and risperidone. All four agents had a statistically significant effect on remission, with an NNT of 9 for aripiprazole, quetiapine, and risperidone. OFC had an NNT of 19, a finding of more questionable clinical relevance. Adverse effects were present, including akathisia (aripiprazole), sedation (quetiapine, OFC, and aripiprazole), metabolic derangement (quetiapine and OFC), and weight gain (all four agents, particularly OFC). Overall, the benefit of atypical antipsychotic augmentation was deemed to be small to moderate, with no clear benefit with regard to quality of life or functional impairment.

Adjunctive therapy with lithium is another long-standing strategy to achieve remission from an MDE. A systematic review and meta-analysis by Nelson *et al.* (2014) examined lithium augmentation of TCAs as well as second-generation antidepressants. The study revealed that lithium augmentation was superior to placebo augmentation of TCAs or second-generation antidepressants, with a pooled OR of 2.89 and remission rate of 46.1% in the lithium augmentation groups, compared with 25.4% in the placebo augmentation group. The World Federation of Societies of Biological Psychiatry guidelines for MDD state that "lithium augmentation should be administered for 2-4 weeks in order to allow assessment of the patient's response. The recommended lithium serum target levels are 0.6 to

0.8 mmol/L. In case of response, lithium augmentation should be continued for at least 12 months" (Bauer *et al.* 2013). Lastly, lithium is well known to reduce the odds of suicide completion, a finding that originated from bipolar outcome studies (Grof and Muller-Oerlinghausen 2009). A meta-analysis by Guzzetta *et al.* (2007) of lithium exposure in 329 pooled patients with MDD found the overall risk of suicide completions and attempts to be 88.5% lower in patients taking lithium than in patients without lithium exposure. For this reason, lithium augmentation should be considered for depressed patients struggling with persistent suicidal ideation.

Finally, thyroid hormone augmentation with triiodothyronine (T_3) is yet another augmentation strategy for MDD. The Sequenced Treatment Alternatives to Relieve Depression (STAR*D) trial included T_3 augmentation versus lithium augmentation at level 3, and reported a 24.7% remission rate (nonsignificant trend toward superiority) and better relative tolerability with T_3 (Gaynes *et al.* 2009). A review by Connolly and Thase (2011) concluded that T_3 augmentation has efficacy for TCA nonresponders, with an NNT "essentially equivalent to that of lithium." However, the authors also noted that there remains a paucity of positive randomized controlled trials (RCTs) supporting the routine use of T_3 by euthyroid patients. For this reason, screening patients for high normal thyroid-stimulating hormone levels or known subclinical hypothyroidism with co-occurring depressive symptoms (especially treatment-resistant depression [TRD]) may prove fruitful. Adding either T_3 or thyroxine (T_4) with a target thyroid-stimulating hormone level below 2.5 mIU/mL, perhaps < 2 mIU/mL, may increase rates of remission (Cohen *et al.* 2018).

Managing Treatment-Resistant Major Depressive Disorder

An unfortunate reality in the treatment of major depressive disorder is that approximately one-third of patients do not achieve remission after two adequate antidepressant interventions with drugs from different classes. This fact was well highlighted in the STAR*D trial, the largest National Institutes of Health-funded depression trial in history, and serves as the working definition of TRD (Gaynes *et al.* 2009). After two failed antidepressant interventions in STAR*D, including multiple antidepressant classes and cognitive-behavioral therapy, remission rates dropped from 31% to 14%. This pivotal point in treatment predicts not only lower remission rates with subsequent interventions but also high rates of relapse and greater medication intolerance (Conway *et al.* 2017; Rush *et al.* 2006). Additionally, TRD is associated with higher risk for overall psychiatric and medical comorbidity, increased health care costs, and elevated risk of death from medical illness and suicide (Greden 2001).

For patients struggling with presumed TRD, it is first important to ensure that pseudoresistance has been ruled out to the extent possible. Assuming that practical factors limiting response have been reviewed (see Table 48-2), it is important for the clinician to carefully review the treatment history, examining it for novel therapeutic interventions that have not been previously explored. This might involve a novel trial with a TCA or MAOI; augmentation with an atypical antipsychotic, thyroid hormone, or lithium; combination therapy with another antidepressant; or the addition of evidence-based psychotherapy, neuromodulation, or, in select cases, ketamine or esketamine therapy. Of all these options, ECT remains the most powerful and effective treatment option for TRD and is reviewed in the next section.

Intravenous ketamine infusion has shown potential in the acute relief of depressive symptoms and suicidal ideation, so it is of therapeutic interest in TRD. A trial comparing single, repeated, and maintenance ketamine infusions for TRD showed that a single ketamine infusion, versus an active midazolam comparator, correlated with significantly greater depressive symptom reduction, peaking at 24 hours and abating by day 7 (Phillips *et al.* 2019). All subjects relapsed before entering the repeated infusion phase, with subsequent restoration of antidepressant efficacy upon resuming thrice-weekly ketamine infusions. Although benefit was maintained in ketamine responders over the next 30 days with weekly maintenance infusions, uncertainty remains about long-term toxicity and abuse potential, given that ketamine has been shown to modulate the endogenous opioid system in addition to antagonizing *N*-methyl-D-aspartate (NMDA) receptors (Williams *et al.* 2018).

Intranasal esketamine, the *(S)*-isomer of racemic ketamine, was approved by the FDA for the treatment of TRD in 2019, with efficacy demonstrated in one Phase III trial comparing esketamine plus a novel antidepressant versus placebo plus a novel antidepressant (Popova *et al.* 2019). Although exciting in some respects, mainly because of the relative ease of outpatient administration, the approval was unusual in that the FDA typically requires two positive Phase III trials before approval. In two prior Phase III studies, esketamine failed to separate from placebo, and despite showing Montgomery-Asberg Depression Rating Scale (MADRS) change scores similar to those in the pivotal study that compelled the FDA to approve esketamine, the effect sizes were notably in the mild range (Schatzberg 2019). Other noteworthy criticisms have been raised about the early esketamine trials, including a published commentary by Turner (2019), who called attention to an "arguably lax regulatory definition" of TRD that included subjects with two within-class (i.e., SSRI) drug failures, a modest 4-point MADRS reduction, enrichment of the randomized withdrawal trial (3,003) with esketamine responders, an outlier trial site in Poland with "a 100% rate of placebo arm relapses," and a standardized mean difference of change in MADRS score inferior to those of aripiprazole and quetiapine augmentation. Compounding these concerns about the fidelity of the outcome data, there were three patients who completed suicide in the active intervention arm (compared with zero in the placebo group), one fatality by motorcycle accident, and two other deaths from cardiovascular complications (U.S. Food and Drug Administration 2019). Although none of the six trial deaths were directly attributed to esketamine, the mortality rate in the trial was worrisome. Overall, despite esketamine's widespread use for TRD, its role remains unclear, especially because long-term exposure data are still being collated to evaluate for negative consequences of chronic exposure.

Somatic Therapies

Somatic therapies are nonpharmacological treatments that directly stimulate the brain in an effort to reduce psychiatric symptoms. ECT is the oldest and most efficacious form of neurostimulation, whereby an electrical stimulus is applied to the brain, with subsequent induction of a brief generalized seizure. Although ECT is classically used in the context of multiple antidepressant failures, it can be used as a first-line therapy in certain situations including imminent suicidality, malnutrition, severe postpartum depression, or agitated psychosis (American Psychiatric Association Task Force on Electroconvulsive Therapy 2001; Kellner *et al.* 2012). Patient preference for ECT should also be considered because certain people may prefer to use ECT if it has been effective for prior depressive episodes. ECT response rates are very high, typically in the 70%-80% range, and it is clearly superior to pharmacological interventions, although it is more invasive and requires anesthesia, similar to other brief medical procedures (Milev *et al.* 2016). Despite substantial advances in ECT technique, such as unilateral electrode placement and ultrabrief-pulse-width stimulation, tolerability concerns, namely anterograde and retrograde amnesia, are barriers to early and widespread use. Thus, ECT is commonly used at a very late stage in MDD, a practice that has been called into question given ECT's documented superiority compared with other therapies (Beale and Kellner 2000).

Repetitive transcranial magnetic stimulation (rTMS) is less invasive form of brain stimulation that can be safely performed on an outpatient basis without anesthesia. Traditional rTMS sends pulses of electrons through a "figure of eight" copper wire coil to create trains of strong (1-2.5 tesla) magnetic pulses that penetrate the cortex up to 2 cm in depth, resulting in underlying neuronal depolarization. Both high-frequency "excitatory" and low-frequency "inhibitory" rTMS delivered to the left and right dorsolateral prefrontal cortex, respectively, have demonstrated efficacy in treating MDD, although only high-frequency rTMS to the left dorsolateral prefrontal cortex is FDA approved for patients with MDD after a single antidepressant failure (Berlim *et al.* 2014). A standard rTMS course delivers a minimum of 3,000 pulses per session, 5 days per week over 4-6 weeks, for a total of 20-30 sessions (McClintock *et al.* 2018). The lack of anesthesia and the ability to safely drive immediately after the procedure make rTMS an attractive alternative to more invasive brain stimulation procedures, such as ECT. However, rTMS response and remission rates resemble those of antidepressant trials and may not be sufficient for severe, refractory depression (Grammer *et al.* 2015). Recent developments in TMS have led to the approval of a new protocol involving a modified stimulation pattern, intermittent theta burst stimulation (iTBS), that reduces delivery time from 15-45 minutes to 1-3 minutes (Milev *et al.* 2016). iTBS, now also FDA approved for TRD, was shown to be noninferior to traditional rTMS, so the reduced delivery time is especially attractive to clinicians because more patients may be treated in a single working day (Blumberger *et al.* 2018). Burgeoning research on iTBS, including multiple daily treatments and functional connectivity-guided functional MRI targeting, may shorten iTBS treatment courses from weeks to days and optimize remission rates even further (Cole *et al.* 2020).

Vagus nerve stimulation (VNS) is an invasive therapy for TRD that was FDA approved in 2005 for chronic or recurrent depression that has not adequately responded to four or more adequate antidepressant treatments (American Psychiatric Association 2009). VNS involves surgically implanting a small lead wire in the neck, attached to the afferent fibers of the left vagus nerve, and stimulating it with an implanted pulse generator placed subcutaneously in the chest or axilla. A 5-year open-label, nonrandomized, observational registry study of patients with TRD compared VNS versus treatment as usual, demonstrating a significantly higher 5-year cumulative MADRS response rate (67.6%) in the VNS versus the treatment-as-usual group (40.9%) (Aaronson *et al.* 2017). This long-term trial highlighted the importance of long-term stimulation as opposed to short-term stimulation, which is less effective. The average study patient had experienced an average of 8.2 depression treatment failures, so VNS therapy may offer hope for functional improvement in the setting of profound TRD, although the surgical invasiveness and specialized skills needed to implant and program VNS are limiting factors.

Deep brain stimulation involves the surgical implantation of paired electrodes into specific bilateral brain structures (i.e., subcallosal cingulate, ventral capsule/ventral striatum, medial forebrain bundle) in an effort to modulate the neural network implicated in major depressive disorder (Drobisz and Damborska 2019). The electrodes are programmed to deliver small electrical pulses to the target areas via an implanted pulse generator in an effort to positively influence mood network dysfunction noted in prior imaging studies. Deep brain stimulation outcomes for TRD have been mixed in the setting of variable stimulation targets, problems with study design and surgical planning, and incomplete understanding of brain networks implicated in TRD on a general and individual level (Filkowski and Sheth 2019). However, improvements in imaging techniques, individualized targeting, and a shift to a "systems/circuits perspective" in psychiatric neuroscience research create promise for this intervention (Widge *et al.* 2018).

BLT is a first-line therapy for MDD with seasonal pattern (formerly known as seasonal affective disorder) and may have a role as a monotherapy or combination therapy

along with an antidepressant in nonseasonal MDD (Lam *et al.* 2016). Morning administration of 30 minutes of BLT with a 10,000-lux light box affords the best chance of remission and may also be efficacious for antepartum and chronic depression (Pail *et al.* 2011). The nonpharmacological nature of BLT is an attractive option for patients who are demoralized by numerous failed antidepressant trials or have exposure concerns such as pregnancy.

In summary, ECT remains the most efficacious somatic therapy for MDD and TRD, but ongoing work in brain stimulation research adds hope for less invasive and more tolerable treatment options for the most treatment-resistant patients. Earlier consideration of neuromodulation treatment is an important option, if not a cultural shift in the field, as it is critical to combat symptoms aggressively before they become chronic and treatment resistant.

Psychotherapies

Cognitive-Behavioral Therapy

Cognitive-behavioral therapy (CBT) was developed by Aaron Beck as a time-limited alternative to open-ended psychoanalytic psychotherapy. By design, CBT was structured for compatibility with RCT investigation and subsequently has been evaluated in numerous RCTs. The aim of CBT is to teach patients how to actively monitor themselves for automatic thoughts, identifying and reformulating extreme or negative thoughts and assumptions about one's self, situation, or future that correlate with unpleasant feelings and unhelpful behaviors. Behavioral interventions are embedded in the therapy as "homework" exercises designed to promote healthy engagement and behavioral activation and minimize withdrawal. For the treatment of acute depression, a meta-analytic evaluation of pooled outcome trials found a medium effect size for CBT relative to a variety of control conditions, with an NNT of 2.75 (Driessen and Hollon 2010). A major advantage of CBT in comparison with pharmacotherapy is the apparent enduring protective effect against relapse and recurrence after the end of active treatment (Lynch *et al.* 2010). Combination therapy with CBT plus antidepressants is known to be superior to pharmacotherapy alone irrespective of the psychotherapy modality (Cuijpers *et al.* 2014).

Interpersonal Therapy

Interpersonal therapy (IPT) was developed by Dr. Gerald Klerman and colleagues in the 1970s, initially as part of a study evaluating the efficacy of a TCA, with and without psychotherapy, for the maintenance treatment of unipolar depression in outpatients (Weissman 2020). Dr. Klerman's team defined a time-limited therapy with a clearly defined procedure (manual) so that psychotherapists could be trained to deliver it with high reliability across various settings. IPT focuses on four important areas: grief, role transitions, role disputes, and interpersonal deficits. In a meta-analysis by

Cuijpers *et al.* (2016), IPT had moderate to large effects compared with other psychotherapies in the treatment of patients with acute-phase depression, preventive effects against development of an MDE in patients with subclinical depressive symptoms, and noninferiority compared with CBT. A possible disadvantage of IPT compared with CBT is that IPT may be effective for relapse prevention only while it is continued (Frank *et al.* 2007).

Mindfulness-Based Cognitive Therapy

Mindfulness-based cognitive therapy (mbCT) is a newer psychotherapy that integrates selected elements of CBT for depression with the application of mindfulness meditation (van der Velden *et al.* 2015). Patients are encouraged to adopt a new way of relating to thoughts and feelings, placing little emphasis on changing specific cognitions, and findings from multiple research trials suggest efficacy for relapse prevention for patients with recurrent depression (Sipe and Eisendrath 2012). A meta-analytic review of pooled mbCT studies revealed large, clinically significant effects for mbCT in treating depression, with maintenance of gains at follow-up and smaller attrition rates in comparison with other cognitive and behavioral therapies (Khoury *et al.* 2013). There is also preliminary evidence of mbCT's efficacy in treatment-resistant depression (Eisendrath *et al.* 2016).

Other Psychotherapies

Various other psychotherapy modalities have been evaluated for patients with MDD, including behavioral activation, short-term psychodynamic psychotherapy, acceptance and commitment therapy, motivational interviewing, Cognitive Behavioral Analysis System of Psychotherapy, and self-guided treatments including bibliotherapy and computer-based delivery platforms for psychotherapy (Lampe *et al.* 2013; Parikh *et al.* 2009). Although empirical evidence exists for CBT and IPT, an American Psychological Association resolution from August 2012 recognized that

> comparisons of different forms of psychotherapy most often result in relatively nonsignificant difference, and contextual and relationship factors often mediate or moderate outcomes. These findings suggest that 1) most valid and structured psychotherapies are roughly equivalent in effectiveness and 2) patient and therapist characteristics, which are not usually captured by a patient's diagnosis or by the therapist's use of a specific psychotherapy, affect the results. (American Psychological Association 2012)

Adjunctive Treatments

Complementary and Alternative Medicine Approaches

There are several complementary and alternative medicine approaches for the treatment of major depressive disorder. In general, these agents have not been studied in large-scale, well-powered randomized controlled clinical trials, as is required by the FDA for approval for any psychiatric indication. Some small trials have found evidence of efficacy, and others have not. Preparations of St. John's wort (SJW, *Hypericum perforatum*), a perennial flowering herb naturally occurring in temperate zones across the globe, have been used to treat depression since the 1980s (Nahas and Sheikh 2011). SJW inhibits the reuptake of serotonin and modifies levels of dopamine, norepinephrine, GABA, and other neurotransmitters (Shelton 2009). A 2008 Cochrane Review by Linde *et al.* (2008) confirmed the efficacy of SJW for mild to moderate depression, although care must be taken to not combine SJW with other serotonergic agents, particularly serotonin-modulating antidepressants (SSRIs, SNRIs, TCAs, MAOIs), because of the risk of serotonin syndrome.

Various nutraceuticals (pharmaceutical-grade nutrients) have also been studied as augmentation therapy to traditional antidepressants. In a 2016 meta-analysis by Sarris *et al.* (2016), primarily positive results were found for replicated studies testing *S*-adenosylmethionine, methylfolate, omega-3 polyunsaturated fatty acids (primarily eicosapentaenoic acid or ethyl eicosapentaenoic acid), and vitamin D. Since then, several failed trials with these agents have appeared.

Lifestyle Interventions

The routine psychiatric care of individuals with MDD includes recommendations for lifestyle modification. The optimization of physical activity (particularly with aerobic exercise), healthy dietary modification, regulation of one's sleep-wake cycle, incorporation of mindfulness meditation practice, and the elimination of recreational substance use (including alcohol and nicotine) have all been shown to be beneficial in addition to standard depression treatment (Sarris *et al.* 2014).

Conclusion

Evolution in the scientific understanding of the pathophysiology and treatment of major depressive disorder continues to progress; however, in many ways, advances in genetic and epigenetic research and neuroimaging techniques add even more complexity to the overall picture of this complex array of illness phenotypes. The field is fortunate to have a large treatment armamentarium including numerous antidepressants and various psychotherapy modalities, but despite these tools, a substantial proportion of patients do not receive adequate care or improve after first-or second-line therapies. Because the majority of mental health care in the United States occurs in the primary care setting, it is important to educate primary care clinicians in the basics of psychiatric diagnosis, measurement-based care, and adequate first-line psychopharmacology for depression, particularly because mental health specialists are in short supply. For patients experiencing any degree of treatment resistance, it remains critical for psychiatrists and other mental health clinicians to thoroughly understand the full menu of treatment options that exist to aggressively pursue remission, or else the risk of chronic, disabling disease remains unacceptably high.

For patients who respond to initial therapy but do not experience symptom remission, a full effort should be exerted to effect a complete remission. This effort should include consideration of aggressive antidepressant dosage optimization, switching to a novel antidepressant class, or initiating adjunctive therapy with other antidepressants, lithium, thyroid hormone, atypical antipsychotics, or psychotherapy. The addition of rTMS or iTBS is a relatively new, safe, and tolerable neuromodulation option for moderate depression after a single failed antidepressant trial. For patients with TRD, switching to an older antidepressant class (including TCAs and MAOIs), cautious consideration of ketamine, and referral for ECT are prudent yet seriously underused strategies.

Looking forward, active research in the domains of ketamine preparations and NMDA antagonists, psychedelic compounds, high-dose iTBS, and other novel brain stimulation methods confer hope for even more efficacious therapeutic tools. This combined with translational research from evolving neuroimaging techniques sets the stage for an exciting time in science and, hopefully, a future era of less depressive disease.

CHAPTER 49

Treatment of Bipolar Disorder

Stephen M. Strakowski, M.D.

Paul E. Keck Jr., M.D.

In this chapter, we review treatment options for bipolar disorder, drawing primarily from published randomized, placebo-controlled trials. When such data were lacking, we developed approaches based on results from open trials, naturalistic studies, and expert consensus guidelines. The treatment of bipolar disorder in youth is addressed separately in this textbook (see Chapter 60, "Treatment of Child and Adolescent Disorders," by Wagner and Pliszka).

Although optimal treatment for bipolar disorder includes both medical and nonmedical components (e.g., psychotherapy), effective psychopharmacology is a necessary and required therapeutic backbone of care. No substantive evidence exists to suggest that bipolar disorder can be managed successfully over time simply with psychotherapy or alternative nonmedical approaches. Consequently, the primary focus of this chapter is on psychopharmacology.

As described by Strakowski *et al.* (2020), in order to create an organizational structure geared toward providing the best treatment approaches, we present pharmacological treatments related to 1) the prevention of affective episodes (so-called maintenance therapy) and 2) the treatment of specific affective phases of illness. We are not suggesting that these phases are managed independently. Unlike some psychiatric conditions, in which managing individual symptoms or symptom clusters is the primary approach, in bipolar disorder we recommend first aggressively treating the *diagnosis*, after which addressing individual bothersome symptoms may be warranted. This approach is supported by increasing evidence that the most effective mood-stabilizing (maintenance) drugs tend to be first-line treatments for acute affective episodes. Nonetheless, clinicians must manage acute affective episodes, so we provide approaches for these events as well.

Maintenance Treatment of Bipolar Disorder

Bipolar disorder is defined by the occurrence of mania (type I) or hypomania plus depression (type II). Mania is perhaps the most predictive syndrome, because once it occurs, more than 90% of individuals develop a recurring lifelong affective illness (Goodwin and Jamison 2007). Because of the high risk of recurrence and morbidity associated with mood episodes and interepisode symptoms, maintenance treatment is usually recommended after a single manic episode and certainly after a second major affective episode (Hirschfeld *et al.* 2002). The goals of maintenance treatment include preventing recurrence of acute affective episodes, minimizing interepisode symptoms, optimizing psychosocial function, and preventing suicide (Keck and McElroy 2017). Although acute episodes may initially respond to a single medication, over the longer term and to achieve and sustain optimal recovery, combinations of medications plus psychotherapy are often required. As we have discussed elsewhere, however, even with the likelihood of requiring combination therapy, use of more than three daily psychotropic medications should seldom be necessary--and, in the rare cases where needed, should be prescribed thoughtfully (Strakowski *et al.* 2020).

Lithium

Lithium is the most extensively studied treatment of bipolar disorder in general and relapse prevention specifically. It is FDA approved for treatment of acute mania and relapse prevention in bipolar disorder. Randomized, placebo-controlled trials conducted in the 1960s and 1970s established that lithium provides a fourfold lower risk of relapse than placebo through at least 1 year (Keck *et al.* 2000). More recent studies continue to support these findings that lithium is superior in efficacy to placebo in preventing relapse into mania for as long as 18 months (e.g., Bowden *et al.* 2003; Calabrese *et al.* 2003). Moreover, large-scale, long-term follow-up studies from European lithium clinics, and decades of clinical experience, further support its long-term effectiveness (e.g., Felber *et al.* 2018; Schou 2001). Lithium prevents both manic and depressive episodes and, perhaps uniquely, decreases suicidality (Beynon *et al.* 2009; Muller-Oerlinghausen *et al.* 2005).

Unlike most other treatments, lithium is best managed by carefully monitoring serum levels. The optimal maintenance serum concentration is really not firmly established. Clinical practice and some research suggest that lower concentrations may be acceptable during maintenance than those used when managing acute mania (Malhi *et al.* 2017). However, Gelenberg *et al.* (1989) and Keller *et al.* (1992) found that levels of 0.4-0.6 mEq/L were associated with a two-to threefold increased relapse rate, and greater likelihood of subsyndromal symptoms, compared with levels of 0.8 mEq/L or higher. However, Perlis *et al.* (2002) reanalyzed the Gelenberg *et al.* (1989) study and found that abrupt drops in serum lithium levels, whether due to random reassignment or due to nonadherence, were the most powerful predictors of relapse, rather than serum levels per se. Unfortunately, side-effect risks are typically directly correlated with serum concentrations, so balancing these two competing needs of effective long-term treatment requires careful communication with the treated individual and diligent clinical oversight. The optimal lithium level will prevent relapse while minimizing both subsyndromal symptoms and bothersome side effects; this dosing may vary with symptoms over time and typically requires diligent long-term course-of-illness documentation to determine the best approach for each treated individual.

Common side effects associated with acute treatment with lithium include nausea, vomiting, tremor, somnolence, weight gain, and the perception of cognitive slowing. Lithium may interfere with thyroid function and exacerbate renal disease; consequently, thyroid and renal function must be regularly monitored during long-term lithium administration.

Antiepileptics

Although several antiepileptic (anticonvulsant) medications are commonly used for treating bipolar disorder, long-term relapse prevention studies are relatively few, and only *lamotrigine* is FDA approved for maintenance therapy in bipolar disorder. Two large 18-month double-blind, placebo-controlled relapse prevention trials comparing lamotrigine (200-400 mg/day) with lithium (0.8-1.1 mEq/L) found that lamotrigine, but not lithium, was superior to placebo in preventing depressive episodes (Bowden *et al.* 2003; Calabrese *et al.* 2003). In contrast, lithium, but not lamotrigine, was superior to placebo in preventing manic episodes. However, in a recent meta-analysis of both lamotrigine and lithium for relapse prevention, Oya *et al.* (2019) demonstrated that both lithium and lamotrigine were superior to placebo for reducing relapse into any mood episode, with lithium demonstrating greater numerical superiority overall. Finally, Calabrese *et al.* (2000) conducted a 6-month placebo-controlled relapse prevention study of lamotrigine (mean dosage = 288 mg/day) in 182 patients with rapid-cycling bipolar I or II disorder. There was no significant difference between the lamotrigine and the placebo treatment groups in time to need additional medications for recurrent mood symptoms.

The primary side-effect concern for lamotrigine is emergence of a rash that can, in rare cases, be life-threatening (e.g., Stevens-Johnson syndrome). A review by Bloom and Amber (2017) of lamotrigine treatment of epilepsy and bipolar disorder concluded that 8.3% of 18,698 study participants from 122 studies developed a rash, with 0.04% developing Stevens-Johnson syndrome. These findings are consistent with those from a retrospective analysis of the nearly 1,200 individuals who received lamotrigine in the bipolar disorder trials mentioned in the previous paragraph, which found that 8.3% developed a benign rash (Calabrese *et al.* 2002). Among the

1,955 individuals receiving lamotrigine in open-label settings, 0.1% developed a rash requiring hospitalization (Calabrese *et al.* 2002). Notably, 6.4% of the 1,056 individuals receiving placebo in these studies also developed a rash.

As mentioned, no other antiepileptic is FDA approved for relapse prevention in bipolar disorder. The only large double-blind randomized, placebo-controlled maintenance study of *divalproex* in bipolar I disorder found no significant difference in time to new mood episodes among divalproex, lithium, and placebo (Bowden *et al.* 2000). The study had a number of design concerns that limited interpretation, however (Keck and McElroy 2017). In other controlled studies, Tohen *et al.* (2003b) found divalproex and olanzapine to exhibit comparable relapse prevention efficacy over 47 weeks, and in a 20-month study of rapid-cycling bipolar disorder, Calabrese *et al.* (2005b) found comparable rates of relapse between divalproex and lithium. However, in a 2013 Cochrane Review (Cipriani *et al.* 2013), the authors concluded that there was insufficient evidence that valproate monotherapy is superior to placebo in relapse prevention or long-term treatment efficacy in bipolar disorder. It was also unclear if the addition of valproate significantly enhanced the efficacy of lithium monotherapy for relapse prevention. No new large-scale studies have changed those conclusions.

As with lithium, serum blood concentrations are used in the management of divalproex treatment, although the therapeutic range for this medication is wide and not well defined for bipolar disorder, mainly having been extrapolated from epilepsy treatment. In the absence of positive large-scale studies of relapse prevention with divalproex, it is no surprise that the optimal maintenance valproic acid concentration in bipolar disorder is unknown. Current practice usually consists of titrating to serum concentrations of 50-125 mg/mL and, as with lithium, balancing relapse and subsyndromal symptom prevention against minimization of side effects (Hirschfeld *et al.* 2002).

Divalproex is generally well tolerated. Common side effects include somnolence, nausea, vomiting, tremor, weight gain, and cognitive slowing. Enteric-coated and extended-release formulations (the latter requiring a 20% dosage increase to be equivalent to immediate-release formulations) have better tolerability compared with valproic acid formulations. Rare serious adverse events include pancreatitis, thrombocytopenia, significant hepatic transaminase elevation, hyperammonemic encephalopathy in individuals with urea cycle disorders, and hepatic failure. Treatment with valproate appears to pose an increased risk of polycystic ovary syndrome and teratogenicity, so its use in young women is limited (Strakowski *et al.* 2020).

Carbamazepine has been used for treating bipolar disorder for more than four decades, yet large, well-designed studies supporting its efficacy for long-term maintenance therapy are limited. Although several older studies, and a few smaller more recent ones, suggested that carbamazepine may have relapse prevention efficacy, especially for mania, these studies are methodologically very limited (Dardennes *et al.* 1995; Grunze *et al.* 2021). Like lithium, carbamazepine has a relatively narrow therapeutic index, so serum levels (target range = 4-12 mg/mL) must be monitored. Complicating the management of serum levels is the fact that carbamazepine eventually accelerates its own metabolism, requiring dosage adjustments.

Common side effects of carbamazepine include diplopia, blurred vision, ataxia, somnolence, fatigue, and nausea. Less common side effects include rash, mild leukopenia and thrombocytopenia, and hyponatremia. Rare serious adverse events include agranulocytosis, aplastic anemia, hepatic failure, pancreatitis, and exfoliative dermatitis. Ultimately, carbamazepine lacks sufficient positive long-term data to offset concerns of tolerability, complex drug-drug interactions, and the need to carefully monitor serum blood levels within a narrow therapeutic range (Strakowski *et al.* 2020). It may be less well tolerated than other treatments as well (Strakowski *et al.* 2001). The related antiepileptic oxcarbazepine, although better tolerated, simply lacks sufficient data supporting a role in the treatment of bipolar disorder, and particularly long-term treatment (Grunze *et al.* 2021).

Atypical Antipsychotics

Several recent articles have described a dramatic decline in the prescription of lithium for bipolar disorder over the past two decades, with a concurrent expanded use of the so-called second-and third-generation antipsychotics (see, e.g., Rhee *et al.* 2020). These medications are generally viewed as easier to prescribe and have been widely marketed, although there is no evidence of their superiority to lithium for long-term management. Unlike the historic (typical) dopamine D_2 antagonist antipsychotics (previously known as "neuroleptics"), these later-generation medications appear, at the least, to lack depressogenic effects, and at the most, to potentially possess antidepressant effects.

Olanzapine was the first of these to gain an FDA indication for relapse prevention. Tohen *et al.* (2005) found that olanzapine was comparable to lithium for relapse prevention in a 1-year comparison trial and comparable to divalproex in a 47-week comparison trial (Tohen *et al.* 2003b). Olanzapine exhibited superiority over placebo in preventing both manic and depressive episodes over 48 weeks (Tohen *et al.* 2006), leading to FDA approval for this indication. Olanzapine combined with lithium or divalproex was superior in efficacy to placebo and to monotherapy with either lithium or divalproex for relapse prevention over 18 months in individuals who initially responded to the active combination acutely (Tohen *et al.* 2002b) and then were re-randomized (Tohen *et al.* 2004). However, the olanzapine-treated group exhibited twice the weight gain of the monotherapy groups, and weight gain and associated metabolic syndrome are problematic with long-term olanzapine therapy in general. Recently, the combination drug (Lybalvi) of olanzapine 5-20 mg plus samidorphan 10 mg was also approved for the maintenance treatment of bipolar disorder (Citrome *et al.* 2021). Samidorphan is a m opioid antagonist. The combination appears to have less weight gain liability than olanzapine monotherapy.

The partial dopamine D_2 antagonist, and so-called third-generation antipsychotic, *aripiprazole* is also FDA approved for maintenance therapy as oral and long-acting injectable formulations. This approval arose from studies in which aripiprazole was superior to placebo in preventing manic relapse over a 6-month follow-up period in individuals with bipolar disorder initially stabilized on aripiprazole monotherapy for an acute manic or mixed episode (Keck *et al.* 2006, 2007). Of note, however, for depressive relapse, aripiprazole did not exhibit a significant difference from placebo. In a 52-week study, the long-acting injectable formulation (Maintena) was superior to placebo injection in increasing time to recurrence of any mood episode and in percentage of patients experiencing a recurrence of any mood episode (Calabrese *et al.* 2017). Aripiprazole is generally well tolerated, although it commonly causes gastrointestinal distress at drug initiation (often requiring a low-dose start with titration over time) and akathisia. Aripiprazole has also been shown to be effective for maintenance treatment as adjunctive treatment with lithium or divalproex (Vieta *et al.* 2010b).

Asenapine has controlled clinical trial evidence supporting FDA approval for monotherapy maintenance treatment of bipolar disorder, suggesting that it may be a useful compound for relapse prevention, although, again, like most other antipsychotics, its effects are perhaps stronger for mania than for depression prevention (McIntyre *et al.* 2010; Szegedi *et al.* 2018). Asenapine can be sedating and may have a higher risk for extrapyramidal side effects (EPS) than other second-and third-generation antipsychotics (Vieta and Montes 2018).

In two randomized controlled trials, the long-acting injectable formulation of *risperidone* was superior in efficacy to placebo in prevention of relapse, both as monotherapy and as adjunctive therapy (Quiroz *et al.* 2010; Vieta *et al.* 2012), and is FDA approved for this indication. Risperidone produces some sedation and has a relatively high risk for EPS, particularly at dosages of 6 mg/day or higher (Hirschfeld *et al.* 2004; Khanna *et al.* 2005; Yatham *et al.* 2003).

It also elevates prolactin more than do other second-generation antipsychotics, although the clinical impact of the laboratory measure is not clear. Similarly, the risperidone metabolite paliperidone, in the extended-release formulation, may also be efficacious as a maintenance treatment in bipolar disorder (Berwaerts *et al.* 2012a), although it is much less studied.

Quetiapine and *ziprasidone* in combination with lithium or divalproex have both been demonstrated to potentially increase time to relapse or intervention in bipolar disorder compared with lithium or divalproex monotherapy (Bowden *et al.* 2010; Suppes *et al.* 2009; Vieta *et al.* 2008). Consequently, both are FDA approved for combination maintenance therapy, although neither is approved for maintenance monotherapy. There is some evidence that quetiapine may have long-term treatment efficacy in relapse prevention of mania and depression (Miura *et al.* 2014). It is generally well tolerated, although it is frequently sedating and is associated with weight gain and metabolic syndrome. Ziprasidone has limited evidence for acute antidepressant efficacy or usefulness in preventing depression relapse as monotherapy. Although less likely to be associated with weight gain, ziprasidone has cardiovascular effects that have to be managed.

Neuromodulatory Therapies

Recent interest in neuromodulatory therapies in psychiatry has continued to increase, although the utility of these technologies for bipolar disorder maintenance treatment is not adequately studied. The oldest of these, electroconvulsive therapy (ECT), is clinically used at times in the maintenance treatment of bipolar disorder but has never been systematically studied in a randomized controlled trial. Several naturalistic studies suggest that maintenance ECT may be a useful treatment alternative for patients whose symptoms are inadequately responsive to pharmacotherapy (Keck and McElroy 2017; Schwarz *et al.* 1995; Vanelle *et al.* 1994). ECT is relatively well tolerated, although it is associated with memory loss, especially with bilateral stimulation. In more recent research, repetitive transcranial magnetic stimulation (rTMS) is being investigated for use in bipolar disorder. However, there are no adequate controlled relapse prevention studies to date to allow determination of the role of rTMS in long-term maintenance treatment of bipolar disorder (Gold *et al.* 2019).

Psychotherapy

Although pharmacotherapy is necessary and critical in the management of bipolar disorder, alone it is rarely sufficient. Bipolar disorder creates significant psychosocial disruption, and, generally, the addition of an evidence-based psychotherapy appears beneficial (Geddes and Miklowitz 2013; Yatham *et al.* 2018). Consequently, for maintenance treatment, the combination of therapy and medications is recommended. Several specific adjunctive psychosocial interventions have been demonstrated to improve long-term outcomes in bipolar disorder (reviewed in O'Donnell and Miklowitz 2020). The best-studied of these include group psychoeducation, interpersonal and social rhythm therapy (IPSRT), family-focused therapies (FFTs), cognitive-behavioral therapies (CBTs), and, more recently, mindfulness-based CBT approaches (O'Donnell and Miklowitz 2020; Xuan *et al.* 2020). Several of these have been examined in large randomized controlled trials conducted over 1-to 2-year follow-up periods. In general, studies suggest that these psychotherapy modalities tend to increase treatment adherence, reduce or delay mood episode recurrence (particularly depression), and improve function when used adjunctively with medications (as compared with use of medications alone). Specifically, efficacy for improved longer-term outcomes has been shown relatively consistently with IPSRT (Frank *et al.* 2005; Swartz *et al.* 2018), FFT (Kim and Miklowitz 2004; Miklowitz *et al.* 2003), and group psychoeducation (Colom *et al.* 2003, 2009), but less consistently with CBT (Jones *et al.* 2015; Lam *et al.* 2005; Scott *et al.* 2006), including mindfulness-based CBT (Xuan *et al.* 2020).

Treatment of Manic and Mixed Episodes

Mania is often a medical emergency and frequently requires inpatient care to ensure the affected individual's safety, to initiate treatment, and to support family members. Mixed episodes comprise both depressive and manic symptoms and may increase the risk of suicide as well as other negative outcomes. With these risks in mind, the primary goal of treatment of manic and mixed episodes is establishing a safe treatment environment, followed by rapid symptom reduction, leading to symptom remission and recovery and restoration of psychosocial and vocational functioning (Hirschfeld *et al.* 2002).

Perhaps because it is dramatic and potentially life-threatening, and because mania fortunately responds to antidopaminergic treatments (i.e., antipsychotics), the treatment of mania is the most extensively studied phase of bipolar illness. Consequently, a number of FDA-approved treatment options are available (Table 49-1). Moreover, individuals in mixed states were often included in the FDA registration trials, so that the same treatments apply to these more complex cases; in fact, there are no FDA-approved treatments for mixed states only. Finally, the treatment of hypomania is little studied, in part because individuals with hypomania rarely seek care. Consequently, our discussion of treatment of mania, at this time, also applies to the treatment of mixed episodes and hypomania, so the latter will generally not be discussed further.

TABLE 49-1. Commonly used pharmacological treatments in bipolar disorder, by phase of illness

Medication	Mania	Depression	Maintenance
Lithium	X, Y	A	X, Y
Antiepileptics			
Divalproex	X	B	B
Carbamazepine	X	C	B
Lamotrigine	D	A	X
Atypical antipsychotics			
Risperidone	X, Y	C	X[1]
Olanzapine	X, Y	X[2]/B[3], Y	X[4]
Ziprasidone	X	D	X[5]
Quetiapine	X, Y	X	X[5]
Aripiprazole	X, Y	D[6]	X

Medication	**Mania**	**Depression**	**Maintenance**
Lurasidone	C	X, Y	C
Asenapine	X, Y	C	X
Paliperidone	A	D	B
Clozapine	C	D	C
Cariprazine	X	X	D
Brexpiprazole	C	D	D
Conventional antipsychotics			
Chlorpromazine	X	D	D
Haloperidol	A	D	D

Note: X = FDA approved for this phase; if not FDA approved, then: A = replicated double-blind placebo-controlled clinical trial or meta-analysis demonstrating efficacy; B = at least one double-blind placebo controlled trial demonstrating efficacy; C = uncontrolled trials or expert clinical use/opinion; D = minimal evidence for efficacy or failed trials.

Y = FDA approved for bipolar disorder in youth (typically ages 10-17 years).

[1] FDA approved in slow-release injectable form.

[2] FDA approved in combination with fluoxetine.

[3] As monotherapy.

[4] Also FDA approved in combination with samidorphan.

[5] FDA approved for augmentation of lithium or divalproex.

[6] FDA approved for augmentation therapy in major depressive disorder, not bipolar depression.

Source. Adapted from Strakowski SM, Almeida J, DelBello MP: "Psychopharmacological treatments for bipolar disorder," in *Primer on Bipolar Disorder*. Edited by Strakowski SM, Fleck DE, Adler CM, DelBello MP. New York, Oxford University Press, 2020, pp 189-228.

Pharmacotherapy is the cornerstone of treatment of acute manic and mixed episodes, and in contrast to maintenance treatment, psychotherapies beyond supportive therapy have a limited role, at least during the acute phase. Overall, the widely used and FDA-approved treatments for mania typically lead to improvement in 50%-60% of individuals in 3-4 weeks. However, monotherapy is rarely effective for full recovery and long-term stability, as noted in the last section, and at times combination therapy is necessary to even achieve remission of the acute manic episode (Suppes *et al.* 2005).

Lithium

Lithium was discovered in 1946, largely through an insightful accident, by John Cade, and it revolutionized the care of people with bipolar disorder specifically and how we approach psychiatric illnesses more generally. Following a series of studies in the 1950s, lithium quickly became the mainstay of treatment for acute mania and has remained so for more than 60 years; its superiority to placebo is definitively established (as reviewed in Goodwin and Jamison 2007), and its efficacy has been shown to be equivalent to that of divalproex (Bowden *et al.* 1994), carbamazepine (Lerer *et al.* 1987; Small *et al.* 1991), risperidone (Segal *et al.* 1998), olanzapine (Berk *et al.* 1999), quetiapine (Bowden *et al.* 2005), aripiprazole (Keck *et al.* 2003a), and typical antipsychotics (Garfinkel *et al.* 1980; Johnson *et al.* 1971; Platman 1970; Prien *et al.* 1972; Shopsin *et al.* 1975; Spring *et al.* 1970; Takahashi *et al.* 1975). Importantly, lithium produced improvement in psychotic, as well as manic, symptoms in these trials; consequently, it is the only known medication that treats psychosis in only a single condition (as opposed to the antipsychotics, which work more broadly). Finally, lithium appears to also uniquely decrease the risk of suicide in bipolar disorder (Lewitzka *et al.* 2015). As noted previously, lithium use has dramatically declined in the past 10-20 years; given its unique properties, it is unlikely that this decline is ultimately in the best interest of people with bipolar disorder.

In the treatment of acute mania, lithium response is maximized by titrating to plasma concentrations at the upper end of the therapeutic range (1.0-1.4 mmol/L) as tolerated (Stokes *et al.* 1976). In randomized controlled trials, responders typically demonstrate significant clinical improvement within 1-2 weeks, although full remission often requires additional time (Keck and McElroy 2001).

Antiepileptics

Divalproex and related formulations of valproic acid exhibited superior efficacy in randomized controlled treatment trials of acute bipolar manic or mixed episodes when compared with placebo (Bowden *et al.* 1994, 2006; Brennan *et al.* 1984; Emrich *et al.* 1981; Pope *et al.* 1991), and showed equivalent efficacy to lithium (Bowden *et al.* 1994; Freeman *et al.* 1992), haloperidol (McElroy *et al.* 1996), and olanzapine (Zajecka *et al.* 2002). However, divalproex was inferior to olanzapine in mean reduction of manic symptoms and proportion of individuals achieving remission in a second comparison trial (Tohen *et al.* 2002a). Muller-Oerlinghausen *et al.* (2000) found that valproate augmentation of typical antipsychotics permitted significantly lower mean antipsychotic doses while yielding higher response rates compared with placebo augmentation in the treatment of acute mania.

Acute antimanic response is associated with divalproex plasma concentrations between 50 and 125 mg/L, with some evidence of greater response at the upper end of the therapeutic range (Allen *et al.* 2006; Zajecka *et al.* 2002). However, these dosage ranges were largely extrapolated from epilepsy studies, and specific antimanic dose-finding studies are limited. Consequently, some individuals require dosing outside this range, although side effects become progressively more problematic with plasma concentrations above 125 mg/L. Divalproex initiated at a dosage of 20-30 mg/kg/day has shown good tolerability, and perhaps a more rapid response, than gradual titration from a lower (e.g., 750 mg/day) starting dosage (Hirschfeld *et al.* 1999; Keck *et al.* 1993). This "loading dose" strategy, then, is recommended.

Carbamazepine, as an extended-release formulation, was superior in efficacy to placebo in two large randomized, placebo-controlled multicenter trials (Weisler *et al.* 2004b, 2005). These findings replicated earlier results from a placebo-controlled crossover trial (Ballenger and Post 1978). As noted previously, the complex side-effect profile and the pharmacokinetic and pharmacodynamic properties of carbamazepine often limit its use in the treatment of acute mania and bipolar disorder more generally.

In the only large randomized, placebo-controlled multicenter trial of *oxcarbazepine* in acute mania to date, a 7-week study in children and adolescents, oxcarbazepine was not superior to placebo in terms of reduction of manic symptoms (Wagner *et al.* 2006). Although sometimes used because of its putative similarities in mechanism of action to carbamazepine, while being better tolerated, the use of oxcarbazepine in acute bipolar mania is not supported by evidence from clinical studies.

Antipsychotics

Conventional (First-Generation) Antipsychotics

Chlorpromazine (Klein 1967) and haloperidol (McIntyre *et al.* 2005) were found to be superior in efficacy to placebo in randomized controlled trials of acute mania treatment. Chlorpromazine was first identified as an antipsychotic in a cohort of individuals

with what was in all likelihood psychotic mania but ended up instead being developed primarily for the treatment of schizophrenia, which it revolutionized (Ban 2007). It is FDA approved for the treatment of acute mania, nonetheless. Typical antipsychotics bear the burden of neurological and neuroendocrinological side effects and may carry an increased risk of postmanic depressive episodes (Kukopulos *et al.* 1980). Consequently, although clearly effective in the treatment of acute mania, these medications are not recommended in general for long-term treatment.

Second-and Third-Generation Antipsychotics

The second-and third-generation antipsychotics have become the primary medications used in the treatment of acute mania specifically and in bipolar disorder more generally. All are D_2 receptor antagonists, and this mechanism likely underlies their antimanic properties. These agents are also effective primary treatments for psychotic disorders more generally (e.g., schizophrenia). The atypical antipsychotics olanzapine, risperidone, quetiapine, ziprasidone, aripiprazole, asenapine, and cariprazine have all shown efficacy in the treatment of acute bipolar mania in at least two randomized, placebo-controlled trials. They are all FDA approved for this indication.

Olanzapine was found to be superior in efficacy to placebo (Tohen *et al.* 1999, 2000), superior or equal in efficacy to divalproex (Tohen *et al.* 2002a; Zajecka *et al.* 2002), and comparable in efficacy to lithium (Berk *et al.* 1999; Niufan *et al.* 2008), risperidone (Perlis *et al.* 2006), and haloperidol (Tohen *et al.* 2003a) in mean reduction of manic and mixed symptoms in 3- to 4-week monotherapy trials. Adjunctive treatment with olanzapine was superior in efficacy to placebo in individuals whose symptoms were inadequately responsive to lithium or divalproex (Tohen *et al.* 2002b). The most common side effects associated with olanzapine were somnolence, constipation, dry mouth, increased appetite, weight gain, and orthostatic hypotension.

Risperidone was superior to placebo (Hirschfeld *et al.* 2004; Khanna *et al.* 2005) and comparable in efficacy to olanzapine (Perlis *et al.* 2006), haloperidol (Smulevich *et al.* 2005), and lithium (Segal *et al.* 1998) in mean reduction of manic and mixed symptoms as monotherapy in 3-to 4-week trials. Risperidone was superior in efficacy to placebo as an adjunctive therapy with lithium or divalproex in one controlled trial (Sachs *et al.* 2002), but not in a second (Yatham *et al.* 2003). The rate of EPS associated with risperidone was low when the drug was administered at average dosages up to 4 mg/day (Hirschfeld *et al.* 2004; Sachs *et al.* 2002; Yatham *et al.* 2003), but not when administered at an average dosage of 6 mg/day or greater (Hirschfeld *et al.* 2004; Khanna *et al.* 2005; Yatham *et al.* 2003). Other commonly occurring side effects included prolactin elevation, akathisia, somnolence, dyspepsia, and nausea. Placebo-controlled trials of the extended-release formulation of the atypical antipsychotic *paliperidone* (a risperidone metabolite) in acute mania yielded mixed findings (Berwaerts *et al.* 2011, 2012b; Vieta *et al.* 2010a), and a recent meta-analysis concluded that it does not offer significant benefits over placebo (Chang *et al.* 2017).

Quetiapine was superior in efficacy to placebo as monotherapy for acute mania in two 12-week studies in adults (Bowden *et al.* 2005; McIntyre *et al.*

2005) and was comparable in efficacy to lithium in a 4-week study in adults (Li *et al.* 2008). Similarly, quetiapine was superior in efficacy to placebo as an adjunctive treatment with lithium or divalproex (Sachs *et al.* 2004; Yatham *et al.* 2004). The mean modal dosage of quetiapine associated with antimanic efficacy in most studies was approximately 600 mg/day (Vieta *et al.* 2005b). Quetiapine was also superior to placebo in the reduction of hypomanic or mild manic symptoms among outpatients in an 8-week trial (McElroy *et al.* 2010a).

Ziprasidone was superior in efficacy to placebo (mean dosage = 120-130 mg/day) in two 3-week monotherapy trials in adults with acute mania (Keck *et al.* 2003b; Potkin *et al.* 2005) and comparable in efficacy to haloperidol in a 12-week trial (Ramey *et al.* 2003). Ziprasidone was not superior to placebo as an adjunctive treatment with lithium in a study designed to prove superior onset of action by 2 weeks of treatment (Weisler *et al.* 2004a). *Asenapine* was superior to placebo in mean reduction of manic symptoms in two 3-week trials (McIntyre *et al.* 2009, 2010).

Among the third-generation antipsychotics, *aripiprazole* had significantly greater efficacy in the reduction of manic symptoms compared with placebo in three 3-week trials (Keck *et al.* 2003a, 2007; Sachs *et al.* 2006), and equivalent efficacy compared with haloperidol (Vieta *et al.* 2005a) and lithium (Keck *et al.* 2009) in 12-week comparison trials. Aripiprazole was initiated at 15 or 30 mg/day. *Cariprazine*, a dopamine D_3 and D_2 receptor partial agonist, was superior to placebo in reduction of manic symptoms in three randomized controlled trials (Calabrese *et al.* 2015; Durgam *et al.* 2015; Sachs *et al.* 2015). The most common side effects associated with cariprazine (occurring in more than 10% of subjects and at twice the rate found with placebo) were akathisia, EPS, tremor, dyspepsia, and vomiting.

In general, there are no studies suggesting that any one atypical antipsychotic is more effective than any other in the treatment of acute mania. Side-effect profiles differ, and this may influence choice. As previously reviewed, there are differences in long-term relapse prevention data that may also guide choices for treating mania; namely, it may be prudent to start in the acute phase with a drug that will be used long term. Moreover, in the studies of atypical antipsychotics reviewed, no significant differences in response were seen between individuals with and without psychotic features or between those with manic episodes and those with mixed episodes, except in trials of quetiapine, many of which excluded patients with mixed episodes. The prototypical atypical agent clozapine was reported to have substantial efficacy in several large case series of individuals with treatment-refractory mania (Calabrese *et al.* 1996; Green *et al.* 2000), but clozapine has not been studied in placebo-controlled studies in mania.

Neuromodulatory Therapies

Electroconvulsive therapy is an important and underutilized treatment option for severe mania, particularly with marked psychotic or catatonic symptoms. ECT was superior in efficacy both to lithium (Small *et al.* 1988) and to the combination of lithium and haloperidol (Mukherjee *et al.* 1994) in prospective comparison studies. In addition, ECT in combination with chlorpromazine was superior to sham ECT and chlorpromazine (Sikdar *et al.* 1994). Although these studies were small, their findings are consistent with those of other naturalistic studies of ECT in the treatment of acute mania (Black *et al.* 1987; Thomas and Reddy 1982) as well as clinical practice. There is a risk of neurotoxicity in individuals receiving ECT while receiving lithium; consequently, lithium should be discontinued when ECT is administered (Hirschfeld *et al.* 2002). Other neuromodulatory therapies (e.g., rTMS) have not been studied sufficiently to recommend use during mania.

Treatment of Acute Depressive Episodes

Although bipolar disorder is defined by the occurrence of mania, depressive symptoms dominant the "ill time" of the condition (Judd *et al.* 2002). The goal of treatment of bipolar depression is full remission of symptoms, including preventing suicide (Hirschfeld *et al.* 2002). This straightforward goal is complicated by the limited efficacy of many mood stabilizers (Zornberg and Pope 1993) and antidepressants in the treatment of bipolar disorder (Sachs *et al.* 2007). Ultimately, as suggested earlier, the optimal approach is to aggressively manage the diagnosis by maximizing compounds effective for long-term relapse prevention.

Lithium

Eight of nine placebo-controlled trials conducted in the 1960s and 1970s in people with bipolar I and II disorders found lithium superior in efficacy to placebo in acute bipolar depression (reviewed in Zornberg and Pope 1993). In an analysis of five studies in which it was possible to distinguish "unequivocal" lithium responders from those with partial but incomplete improvement in depression, Zornberg and Pope (1993) reported that 36% had an unequivocal response, compared with 79% who had partial but incomplete benefit.

Second-and Third-Generation Antipsychotics

Quetiapine (300 mg/day and 600 mg/day) is FDA approved for the treatment of bipolar depression; it was superior to placebo in reducing depressive symptoms in four large 8-week multicenter trials involving individuals with bipolar I and II depression (Calabrese *et al.* 2005a; McElroy *et al.* 2010b; Thase *et al.* 2006; Young *et al.* 2010). Although both dosages similarly improved symptoms, the rate of side effects was lower in the 300 mg/day groups compared with the 600 mg/day groups. New episodes of mania were few and similar across all treatment groups, including placebo.

Both *olanzapine* and the *olanzapine-fluoxetine* combination (OFC) were superior to placebo in reducing depressive symptoms in an 8-week trial with depressed bipolar I disorder patients (Tohen *et al.* 2003c). However, the combination treatment was superior to placebo throughout the trial, and was superior to olanzapine monotherapy from week 4 onward; consequently, OFC received FDA approval for this indication. No significant differences in new cases of mania were observed between patients with and without the addition of fluoxetine. Brown *et al.* (2006) compared OFC with lamotrigine (titrated to 200 mg/day) in a 7-week comparison trial in depressed bipolar I disorder patients and observed greater reductions in depressive symptoms in the OFC group. However, the necessary slow titration of lamotrigine makes interpretation difficult (i.e., lamotrigine was underdosed for a significant portion of the study). New cases of mania were not significantly different between the two groups.

Lurasidone was more effective than placebo for the treatment of depressed bipolar I disorder patients in two large FDA registration trials (reviewed by Franklin *et al.* 2015). Notably, the onset of therapeutic effect occurred within the first 2-3 weeks of treatment among responders. Lurasidone is significantly less likely than other atypical agents to produce metabolic side effects, although it is associated with sedation, akathisia, and gastrointestinal side effects.

Cariprazine is a dopamine D_2 and D_3 receptor partial antagonist that is FDA approved for the treatment of depression in bipolar I disorder (reviewed in a meta-analysis by Pinto *et al.* [2020]). It has a relatively high risk for akathisia and gastrointestinal distress but is generally well tolerated and has a low risk of weight gain.

Antiepileptics

Lamotrigine is FDA approved for the prevention of depressive episodes, but not for the treatment of acute depression. In an initial large 7-week randomized, placebo-controlled trial, lamotrigine (at 50 mg/day and 200 mg/day) was superior to placebo in depressed bipolar I disorder patients (Calabrese *et al.* 1999), with no differences among groups in new manic episodes. A second large placebo-controlled, parallel-group, flexible-dose trial involving depression in both bipolar I and II disorder did not find a significant advantage for lamotrigine over placebo, however (Bowden 2001). In a double-blind crossover trial, Frye *et al.* (2000) found lamotrigine superior to placebo in improving depression in individuals with treatment-refractory rapid-cycling bipolar I or II disorder. Lamotrigine was superior to placebo when added to lithium treatment in an 8-week trial in individuals with bipolar disorder and breakthrough depressive episodes (van der Loos *et al.* 2009).

Divalproex has been relatively understudied and has mixed results in bipolar depression. For example, Sachs and Collins (2001) did not find divalproex to be superior in efficacy to placebo in a pilot trial, whereas Davis *et al.* (2005) found divalproex superior to placebo in reduction of depressive and anxiety symptoms in a later pilot study. Bond *et al.* (2010) completed a meta-analysis of available data and concluded that the relative likelihood of response to divalproex was greater than that to placebo (RR = 1.6-2.1). These authors interpreted the results to suggest "preliminary evidence" for efficacy of divalproex for the treatment of bipolar depression.

Carbamazepine has limited data supporting its efficacy in bipolar depression. In two small controlled trials in treatment-refractory bipolar depression, response to carbamazepine was superior to that seen with placebo (Post *et al.* 1986) or lithium (Small 1990). The results of these initial intriguing findings from small studies have not been followed by large placebo-controlled, parallel-group studies. In part, as discussed, the complexities of managing carbamazepine therapy may limit enthusiasm for larger studies.

Antidepressants

The evidence base for the efficacy of standard antidepressant medications for the treatment of depression in bipolar disorder is meager. Recent studies and meta-analyses (e.g., Cheniaux and Nardi 2019; Sachs *et al.* 2007; Sidor and MacQueen 2012) suggest a limited role for these medications in bipolar I disorder. However, antidepressants may have a larger role in depression in bipolar II disorder (Amsterdam and Shults 2005). Notably, switch rates associated with newer antidepressants in short-term studies, in general, appear to be lower than those associated with tricyclic antidepressants (TCAs) in older studies (Thase and Sachs 2000), although efficacy appears no better. Among all of the antidepressants studied, the most substantial evidence for efficacy rests with the monoamine oxidase inhibitor (MAOI) tranylcypromine (Himmelhoch *et al.* 1991), but safety concerns often eliminate this agent from first-line therapy choices (Hirschfeld *et al.* 2002).

Bupropion (Sachs *et al.* 1994) and selective serotonin reuptake inhibitors (SSRIs) (Nemeroff *et al.* 2001) are commonly administered in conjunction with mood stabilizers, so they may have a secondary role in some individuals. At this point in time, the cumulative evidence suggests that antidepressants are at most an adjunctive treatment choice in bipolar depression, even when delivered as a combination drug (i.e., OFC, with fluoxetine considered as an adjunct in this case) (Strakowski *et al.* 2020). Whether there are subtypes of bipolar disorder or subgroups of patients in which antidepressants may play a more prominent role remains to be defined.

Neuromodulatory Therapies

Electroconvulsive therapy is perhaps the most effective antidepressant available, including in the treatment of depressed individuals with bipolar disorder. ECT had significantly greater efficacy than MAOIs, TCAs, or placebo in several randomized controlled trials in patients with bipolar depression (reviewed in Zornberg and Pope 1993). ECT may be particularly indicated for individuals with severe, psychotic, or catatonic symptoms.

Repetitive transcranial magnetic stimulation is FDA approved for treatment of "treatment-resistant depression," but its role in bipolar depression remains undefined. To date, study results are mixed regarding efficacy, and rTMS may be associated with manic switch in some individuals (Gold *et al.* 2019).

Ketamine

Ketamine is an FDA approved anesthetic that has been recently used, in subanesthetic doses, to rapidly improve symptoms, including suicidality, in unipolar and bipolar depression (Grady *et al.* 2018; McIntyre *et al.* 2020). In a nasal administration form, it is FDA approved for treatment-resistant depression in adults, as an adjunct to standard antidepressant therapy. Its role in bipolar disorder remains to be defined.

Psychotherapy

Very few randomized controlled trials of any form of psychotherapy have been conducted for acute bipolar depression (O'Donnell and Miklowitz 2020). Swartz *et al.* (2018) compared IPSRT plus placebo versus IPSRT plus quetiapine in acutely depressed adults with bipolar II disorder. The IPSRT plus quetiapine group improved faster. CBT and interpersonal therapy have demonstrated efficacy in the treatment of unipolar major depressive disorder, but these modalities have been examined only in very small preliminary studies in patients with bipolar depression, thus far without conclusive findings (Cole *et al.* 2002; O'Donnell and Miklowitz 2020; Zaretsky *et al.* 1999). The Systematic Treatment Enhancement Program for Bipolar Disorder (STEP-BD) included a 2-year randomized trial of three intensive psychotherapies--namely, IPSRT, CBT, and FFT. Recovery rates did not differ among therapies, but individuals receiving therapies in conjunction with medication treatment exhibited better recovery from the index depression (Miklowitz *et al.* 2007).

Conclusion

During the past two decades, there has been a steady increase in available treatments for bipolar disorder, although the bulk of studies have been for the treatment of acute

mania. Consequently, a number of medications have demonstrated efficacy in the treatment of acute mania in placebo-controlled trials, either as monotherapy or as an adjunct to mood stabilizers. In addition, evidence suggests that combination therapy with an antipsychotic and another class of mood stabilizer (e.g., lithium) is more rapidly effective, with better overall response rates in acute mania, than either treatment alone. However, whether this effect is "absolute" or simply faster is not known.

In contrast, the treatment of bipolar depression remains one of the least-studied aspects of modern psychiatry, particularly given the prevalence, morbidity, and mortality associated with this condition. Complicating this gap in treatment knowledge, it has become increasingly clear that antidepressants provide only limited efficacy in bipolar disorder, and therefore are suboptimal interventions. Long-term relapse prevention--so-called maintenance therapy--is also understudied; even though a few compounds have received FDA approval for this purpose, lithium remains the best-studied choice.

As noted at the beginning of this chapter, perhaps the most parsimonious approach to managing bipolar disorder is to optimize treatments with proven efficacy, especially efficacy for maintenance therapy. With this approach in mind, combinations of these medications are perhaps the current best practice; as noted in this chapter and elsewhere, however, polypharmacy exceeding three daily medications is generally not recommended. Instead, a careful trial-and-error process to identify the best two-or three-medication combination plus an evidence-based therapy that optimizes function and the amount of time spent in a euthymic state is the best approach. This approach requires careful documentation, a lot of psychoeducation, and a coordinated treatment team (Strakowski *et al.* 2020). Nonetheless, despite a number of persisting gaps in treatment knowledge, the options available for people with bipolar disorder have dramatically expanded, suggesting that better treatments are just over the horizon.

CHAPTER 50

Treatment of Anxiety Disorders

Soo-Hee Choi, M.D., Ph.D.
Murray B. Stein, M.D., M.P.H., FRCPC

Anxiety disorders are one of the most common psychiatric disorders, with a lifetime prevalence of more than 20% (Kessler *et al.* 2005a). The course of anxiety disorders varies. Some patients have transient and subsyndromal symptoms that do not require treatment, whereas others experience significant distress with a chronic and fluctuating course of illness. In this chapter, we review the main findings from double-blind and some open-label trials of psychopharmacological treatment for anxiety disorders.

Panic Disorder

Panic disorder severity and treatment outcomes can be measured with the clinician-or self-rated Panic Disorder Severity Scale (Shear *et al.* 1997). Other widely used measures include the Sheehan Panic and Anticipatory Anxiety Scale (Sheehan 1986) and the self-rated Marks-Mathews Fear Questionnaire (Marks and Mathews 1979). The desired endpoint is full remission, although this is not always attainable. Effective treatment results in reduced emergency department and laboratory resource use (Roy-Byrne *et al.* 2001).

First-Line Pharmacotherapy

Selective Serotonin Reuptake Inhibitors and Serotonin-Norepinephrine Reuptake Inhibitors

In a meta-analysis, Boyer (1995) reported that selective serotonin reuptake inhibitors (SSRIs) were more effective than imipramine and alprazolam in treating panic disorder. However, a meta-analysis by Otto *et al.* (2001) failed to confirm these findings. Evidence is now available in support of the SSRIs citalopram (Wade *et al.* 1997), escitalopram (Stahl *et al.* 2003), fluoxetine (Michelson *et al.* 1998, 2001), fluvoxamine (Asnis *et al.* 2001; Black *et al.* 1993), paroxetine (Ballenger *et al.* 1998; Oehrberg *et al.* 1995; Sheehan *et al.* 2005), and sertraline (Londborg *et al.* 1998) as well as the nonselective serotonin reuptake inhibitor clomipramine (Lecrubier *et al.* 1997a). Fluoxetine, paroxetine, and sertraline are FDA approved for the treatment of panic disorder.

The extended-release formulation of venlafaxine, a serotonin-norepinephrine reuptake inhibitor (SNRI), demonstrated greater efficacy than placebo for patients with panic disorder in a 10-week trial (Bradwejn *et al.* 2005). In addition, extended-release venlafaxine was as effective as paroxetine in a 12-week placebo-controlled trial (Pollack *et al.* 2007) and is FDA approved for the treatment of panic disorder. Extended-release venlafaxine is well tolerated, with an adverse-effect profile comparable to that observed when it is used to treat depressive and other anxiety disorders. Although no systematic data are currently available supporting the use of other SNRIs in the treatment of panic disorder, duloxetine and milnacipran significantly alleviated panic disorder symptoms in open trials (Blaya *et al.* 2007; Simon *et al.* 2009).

Patients with panic disorder are often extremely sensitive to the activating effects of antidepressants. They have poor tolerance of symptoms such as palpitations, sweating, and tremor and frequently discontinue treatment or drop out. This problem can almost always be prevented by coprescribing a benzodiazepine (Goddard *et al.* 2001; Pollack *et al.* 2003) or by starting with a low dosage of an SSRI and increasing it gradually as tolerated. The recommended starting dosages of antidepressants for panic disorder are approximately half those given for depressive disorders

(American Psychiatric Association 2010), but dosages should be gradually increased to dosages similar to those used to treat depressive disorders. Because average dosages used to treat anxiety disorders are as high as (or higher than) those used to treat depressive disorders, both physician availability and thorough patient preparation and education are crucial for promptly addressing any uncomfortable side effects. Other common side effects of SSRIs include weight gain, sexual dysfunction, sleep impairment, and potential drug-drug interactions.

Within SSRIs, it is considered that the efficacy is comparable. If a response is not elicited from an SSRI, the subsequent step would entail attempting an alternative SSRI or switching to an SNRI.

Treatment discontinuation can lead to relapse, which mimics panic symptoms and is quite distressing. Gradual dosage reduction is recommended, as are patient education, physician availability, and coping strategies such as cognitive-behavioral therapy (CBT) (Otto *et al.* 1993). Switching to a long-acting SSRI such as fluoxetine may be considered. Serotonin 5-HT_2 or 5-HT_3 receptor antagonists (e.g., mirtazapine, ondansetron) may be used to limit some of the symptoms mediated through these pathways (e.g., insomnia, agitation, gastrointestinal distress).

Other Pharmacological Approaches

Benzodiazepines

The Cross-National Collaborative Panic Study (1992) showed that alprazolam, along with imipramine, was more effective for panic disorder than placebo. Lydiard *et al.* (1992) reported that alprazolam 2 mg/day was more effective than placebo. Efficacy for clonazepam in panic disorder was also demonstrated (Davidson and Moroz 1998; Rosenbaum *et al.* 1997; Tesar *et al.* 1991). Alprazolam and clonazepam are FDA approved for the treatment of panic disorder. Although the evidence was judged to be of low quality, previous Cochrane Reviews reported the superiority of benzodiazepines over placebo in the short-term treatment of panic disorder (Breilmann *et al.* 2019) and comparable efficacy of benzodiazepines and antidepressants for panic symptoms (Bighelli *et al.* 2016). Benzodiazepines are widely prescribed for the treatment of panic disorder, primarily because of their rapid onset of action. However, because of the risks of dependency and withdrawal symptoms, it is suggested that benzodiazepines should be avoided as first-line treatment or should generally only be used for a limited time (American Psychiatric Association 2010; Baldwin *et al.* 2014).

Alprazolam (and other benzodiazepines) are now regarded as a second-line treatment for panic disorder. Problems include sedation at higher dosages, abuse liability, and discontinuation-related distress. Clonazepam has an advantage over alprazolam because of its longer half-life; however, clonazepam can also result in sedation, depression, and discontinuation symptoms. One review has supported a role for clonazepam alone or in combination with SSRIs and/or CBT in the management of panic disorder (Nardi *et al.* 2013).

The use of benzodiazepines is a particular concern for elderly patients. Many elderly individuals are more prone to sedation and falls, which can result in fractures and potential head injury; they are also more likely to experience discontinuation problems.

Tricyclic Antidepressants

Although tricyclic antidepressants (TCAs) are effective (for a review, see Freire *et al.* 2014; Sartori and Singewald 2019), they are considered second-line treatments for panic disorder because of their side effects. Imipramine is the most well studied of the TCAs in panic disorder. Mavissakalian and Perel (1995) found that phobic symptoms responded best if the plasma level of imipramine and desmethylimipramine ranged from 110 to 140 ng/mL, whereas control of panic attacks tended to occur at lower plasma levels. As with SSRIs and SNRIs, low starting dosages in the range of 10-25 mg/day are in order, with gradual titration thereafter per patient tolerance until response is achieved.

Monoamine Oxidase Inhibitors

Sheehan *et al.* (1980) found that phenelzine, along with imipramine, was more effective than placebo in the treatment of panic disorder with agoraphobia. In addition, Lydiard and Ballenger (1987) noted that monoamine oxidase inhibitors (MAOIs) may be superior to TCAs. Although MAOIs may still be the best treatment for some patients, the overall role of MAOIs in managing anxiety disorders is now fairly small because of their potential side effects and drug-drug interactions. The role of the safer

reversible inhibitors of monoamine oxidase A (not available in the United States) in panic disorder is unclear.

Other Drugs

Mirtazapine, a noradrenergic and specific serotonergic antidepressant, demonstrated possible benefit in panic disorder in open trials (Boshuisen *et al.* 2001; Sarchiapone *et al.* 2003) and in a double-blind comparison with fluoxetine (Ribeiro *et al.* 2001). However, double-blind, placebo-controlled trials have yet to be conducted. It is noteworthy that mirtazapine has been associated with the induction of panic attacks in patients with depression undergoing dosage escalation and discontinuation (Berigan 2003; Klesmer *et al.* 2000).

Vortioxetine is a novel atypical antidepressant considered to have a multimodal mechanism of action. This drug demonstrated clinical efficacy in panic disorder in an open-label trial (Shah and Northcutt 2018) but has not been studied in double-blind, placebo-controlled trials.

The 5-HT_{1A} partial agonist buspirone and the anticonvulsant gabapentin were generally ineffective in panic disorder, although gabapentin showed superiority to placebo in a subgroup of patients with severe illness (Pande *et al.* 2000; Sheehan *et al.* 1990). Possible benefit has been reported in open-label trials for other anticonvulsant drugs, including levetiracetam, tiagabine, and valproic acid (Keck *et al.* 1993; Papp 2006; Zwanzger *et al.* 2001). A small double-blind, placebo-controlled trial with tiagabine did not show clinical benefits, although cholecystokinin-tetrapeptide (CCK-4)-induced sensitivity to panic attacks decreased (Zwanzger *et al.* 2009).

Preliminary data suggest that improvement in refractory panic disorder occurs when atypical antipsychotics, such as olanzapine (Sepede *et al.* 2006) or risperidone (Simon *et al.* 2006), are used to augment SSRI treatment or are taken in higher dosages as monotherapy (e.g., olanzapine [Hollifield *et al.* 2005]). In a 2013 randomized, placebo-controlled monotherapy trial of extended-release quetiapine versus divalproex for patients with bipolar disorder and comorbid panic or generalized anxiety disorder, extended-release quetiapine (50-300 mg/day) showed rapid and sustained effects in reducing anxiety symptoms (Sheehan *et al.* 2013). However, a 2015 double-blind, placebo-controlled trial in which extended-release quetiapine was coadministered with an SSRI to patients with SSRI-resistant panic disorder did not support the efficacy of this treatment strategy (Goddard *et al.* 2015).

A 2017 double-blind, randomized placebo-controlled trial of D-cycloserine, a partial *N*-methyl-D-aspartate receptor agonist that potentially augments response to exposure therapy in anxiety disorders, did not demonstrate this effect of improved response to exposure therapy for panic disorder (Hofmeijer-Sevink *et al.* 2017).

Long-Term Management

Maintenance treatment is recommended for at least 12-24 months, if not longer. In a controlled trial of paroxetine, clomipramine, and placebo, 84% of paroxetine-treated patients eventually became panic free over the 9-month study period (Lecrubier *et al.* 1997b). In a 4-year naturalistic follow-up study of 367 patients with panic disorder, greater improvements in panic attacks, phobic avoidance, and daily functioning were observed for those who received continuation treatment for 4 years compared with 1 year (Katschnig *et al.* 1995), suggesting that recovery can continue over several years.

Long-term randomized controlled trials have reported efficacy for citalopram (Lepola *et al.* 1998), clomipramine (Fahy *et al.* 1992), fluoxetine (Michelson *et al.* 1999), paroxetine (Lecrubier *et al.* 1997b; Lydiard *et al.*

1998), and sertraline (Rapaport *et al.* 2001). In a relapse prevention trial following 3 months of successful open-label treatment, Ferguson *et al.* (2007) showed that over the course of 7 months, the rate of relapse with extended-release venlafaxine was 22%, compared with 50% for placebo.

Discontinuation Symptoms

Although there is some similarity between symptoms of relapse and drug withdrawal, the existence of discontinuation symptoms is indisputable. When a decision is made to stop, a slow taper over several weeks is recommended for all antidepressants or other medications being used to treat panic disorder; for some benzodiazepines, it may be necessary to taper the drug over weeks or months. Timing of the taper may be important--it is best done when other variables in a patient's life are as stable as possible. Approaches such as switching to a longer-acting benzodiazepine (e.g., clonazepam), adding an anticonvulsant (e.g., carbamazepine or valproate [Pages and Ries 1998]), and utilizing CBT (Otto *et al.* 1993) have all been used to ameliorate discontinuation symptoms.

Nonpharmacological Approaches

Various elaborations of CBT have demonstrated consistent efficacy for panic disorder, with the common elements being education, cognitive strategies, and exposure to feared sensations and situations (Kaczkurkin and Foa 2015; Pompoli *et al.* 2016). CBT is a first-line choice; even when pharmacotherapy is given as the main treatment, principles of CBT should be incorporated into the management plan. CBT can be of benefit during the process of drug discontinuation and may also lessen the chance of relapse afterward.

Social Anxiety Disorder

Social anxiety disorder (known as social phobia in DSM-IV [American Psychiatric Association 1994]) has a lifetime prevalence of 12% (Kessler *et al.* 2005b). This disorder can be grouped into two types: *generalized* (a term used in DSM-IV but removed in DSM-5 [American Psychiatric Association

2013]) and *nongeneralized* (a performance-only specifier, according to DSM-5). Generalized social anxiety disorder is more common in clinical settings, is usually more disabling, and is associated with greater comorbidity and genetic loading. Most of our knowledge about pharmacotherapy for social anxiety disorder derives from the generalized type, and the literature suggests that different medication approaches may be called for in treating the two subtypes. Social anxiety disorder as described in this section refers to what DSM-IV described as *generalized* social anxiety disorder.

Treatment of social anxiety disorder involves multiple components. For example, treatment requires that 1) symptoms of fear, avoidance, and physiological distress are brought under control; 2) comorbidity is treated; 3) disability and impairment are improved; and 4) quality of life is enhanced. Furthermore, evidence from maintenance and relapse prevention studies has confirmed the value of long-term therapy in treatment responders.

Instruments commonly used to measure treatment response in social anxiety disorder include the clinician-and self-rated versions of the Liebowitz Social Anxiety Scale (Liebowitz 1987), which assesses 24 performance or interpersonal situations for fear and avoidance. A score of 30 or less is considered to equate with remission. The Social Phobia Inventory is a 17-item self-rating instrument that assesses fear, avoidance, and physiological distress (Connor *et al.* 2000) and, like the Liebowitz Social Anxiety Scale, can also be used to measure improvement.

Pharmacotherapy

Most clinicians consider SSRIs and venlafaxine as the first choice for treatment of social anxiety disorder. Second-line drugs include benzodiazepines, other antidepressants (e.g., mirtazapine, MAOIs), and some other drug types (e.g., gabapentin, pregabalin). For performance-only social anxiety disorder, b-blockers or benzodiazepines are considered the first choice.

Serotonergic Drugs

Paroxetine, controlled-release paroxetine, sertraline, controlled-release fluvoxamine, and extended-release venlafaxine are currently FDA approved for the treatment of social anxiety disorder.

In meta-analyses, SSRIs were superior to placebo in terms of response rates and reductions in symptoms, disability, and relapse (Hedges *et al.* 2007; van der Linden *et al.* 2000; Williams *et al.* 2017). The superiority of extended-release venlafaxine over placebo was also shown in two double-blind trials of social anxiety disorder treatment (Allgulander *et al.* 2004b; Liebowitz *et al.* 2005).

A double-blind, placebo-controlled trial of mirtazapine in women showed statistically significant superiority for the drug over placebo (Muehlbacher *et al.* 2005). However, another double-blind, placebo-controlled trial in 60 outpatients with social anxiety disorder who received mirtazapine (30-45 mg/day) failed to demonstrate evidence of efficacy (Schutters *et al.* 2010).

Benzodiazepines

Three major placebo-controlled trials have shown efficacy for benzodiazepines in social anxiety disorder. Gelernter *et al.* (1991) showed a modest increase in response rates for alprazolam over placebo (38% vs. 20%) at a mean dosage of 4.2 mg/day, although alprazolam was generally inferior to phenelzine. Davidson *et al.* (1993) found a substantially greater response rate for clonazepam compared with placebo (70% vs. 20%) in 75 subjects. Bromazepam was also more effective than placebo (Versiani *et al.* 1997). In a double-blind, placebo-controlled trial of augmentation and switch strategies for refractory social anxiety disorder, Pollack *et al.* (2014) found that clonazepam augmentation ([?] 3 mg/day) of sertraline treatment was superior to placebo augmentation and also superior to a switch to venlafaxine, with a higher percentage of patients taking clonazepam plus sertraline achieving remission.

Benzodiazepines provide significant benefits, yet they are not considered first-line drugs because of their more limited spectrum of action (i.e., they are not expected to improve depressive symptoms, which are commonly comorbid in patients with social anxiety disorder) and potential withdrawal difficulties. However, they work rapidly,

are well tolerated, and may be particularly useful for individuals with periodic performance-related anxiety or treatment-resistant social anxiety disorder.

Gabapentin and Pregabalin and Anticonvulsants

Gabapentin and pregabalin produce significant effects in social anxiety disorder. Pande *et al.* (1999) found a superior effect for gabapentin over placebo in a trial using flexible dosing (900-3,600 mg/day, with 2,100 mg/day being the most common final gabapentin dosage), with response rates of 39% and 17%, respectively. Pregabalin also has shown benefit in social anxiety disorder (Feltner *et al.* 2003; Pande *et al.* 2003). Although pregabalin 150 mg/day was no different from placebo, 600 mg/day produced greater effects than placebo, with response rates of 43% and 22%, respectively. A 26-week double-blind, placebo-controlled maintenance trial of pregabalin at a fixed dosage of 450 mg/day showed that pregabalin not only was superior to placebo in maintaining symptomatic improvement but also was relatively well tolerated (Greist *et al.* 2011). Levetiracetam failed to differentiate from placebo (Stein *et al.* 2010). Further work with anticonvulsants is needed, given that these agents are generally well tolerated, safe, and less likely to produce discontinuation symptoms compared with many SSRIs and benzodiazepines.

Monoamine Oxidase Inhibitors

Reversible inhibitors of monoamine oxidase A. Moclobemide, a reversible inhibitor of monoamine type A, is safer than older MAOIs and was shown to be almost as effective as phenelzine and significantly better than placebo (Versiani *et al.* 1992), but it is not marketed in the United States.

Irreversible inhibitors of monoamine oxidase. Phenelzine showed positive benefit in four studies (Gelernter *et al.* 1991; Heimberg *et al.* 1998;

Liebowitz *et al.* 1992; Versiani *et al.* 1992). Response rates for phenelzine were 69%, 85%, 64%, and 65%, respectively, compared with 20%, 15%, 23%, and 33% for placebo; phenelzine overall was shown to have a large effect size (Davis *et al.* 2014). MAOIs (phenelzine or tranylcypromine) should be strongly considered for individuals whose symptoms are nonresponsive to other treatments and who can adhere to the necessary dietary and medication restrictions.

Other Drugs

Olanzapine yielded greater improvement than placebo in a small (*n* = 12) double-blind, placebo-controlled monotherapy trial (Barnett *et al.* 2002). This finding suggests that atypical antipsychotics may deserve further investigation in social anxiety disorder, although their benefits must be weighed against their potential metabolic adverse effects. Although the 5-HT_3 antagonist ondansetron produces a statistically significant effect relative to placebo, it seems to be of limited clinical benefit (Bell and DeVeaugh-Geiss 1994; Davidson *et al.* 1997) but may be used adjunctively in some cases. Buspirone was ineffective in a double-blind trial, with a 7% response rate (van Vliet *et al.* 1997).

Despite their intuitive appeal, b-blockers have shown poor efficacy in treating social anxiety disorder (other than for the performance-only specifier). For example, atenolol failed to separate from placebo in two trials (Liebowitz *et al.* 1992; Turner et al. 1994). b-Blockers do show some value in performance-related social anxiety, perhaps by virtue of their ability to reduce peripheral autonomic arousal and block negative feedback.

Despite earlier studies showing promise for the use of D-cycloserine augmentation of exposure therapy in social anxiety disorder (Guastella *et al.* 2008; Hofmann *et al.* 2006), findings in subsequent studies have been far less encouraging overall (Hofmann *et al.* 2013, 2019; Roque *et al.* 2018).

Connor *et al.* (2006) reported benefit for one-time intradermal bilateral axillary injections of botulinum toxin type A (50 units) for individuals with social anxiety disorder and troublesome axillary hyperhidrosis. The effects persisted over 8 weeks and were superior to placebo for sweating, daily function, and activities. All subjects received concomitant paroxetine for other aspects of social anxiety disorder.

A 4-week Phase III pilot randomized double-blind, placebo-controlled crossover study showed that as-needed use of intranasal PH94B (3b-androsta-4,16-dien-3-ol), a synthetic neurosteroid molecule, was superior to placebo for subjective distress in social anxiety disorder (Liebowitz *et al.* 2016). Further studies on the abuse potential and long-term effects of PH94B are needed to clarify its full utility for social anxiety disorder.

Treatment in Children and Adolescents

Pharmacological approaches to treating social anxiety disorder in children are usually implemented when behavioral approaches have been insufficient to resolve symptoms and improve functioning. One placebo-controlled trial of fluvoxamine in children ages 6-17 years showed that this agent was superior to placebo for social anxiety disorder, generalized anxiety disorder, and their combination: 76% of the fluvoxamine group achieved response, compared with 19% of the placebo group (Walkup *et al.* 2001). Double-blind trials of immediate-release paroxetine (Wagner *et al.* 2004) and extended-release venlafaxine (March *et al.* 2007) have produced positive results in children and adolescents with social anxiety disorder.

A multisite study compared CBT alone, sertraline alone, combination CBT and sertraline, and placebo in 488 children (ages 7-17 years) with a primary diagnosis of separation anxiety disorder, generalized anxiety disorder, or social anxiety disorder (Walkup *et al.* 2008). CBT monotherapy and sertraline monotherapy were each superior to placebo in reducing anxiety symptoms in children (response rates of 59.7% and 54.9%, respectively); however, the combination treatment had the best response rate (80.7% [Walkup *et al.* 2008]). At 24 and 36 weeks of follow-up, the majority of acute responders maintained their response, and the combination treatment maintained its advantage over the CBT and sertraline monotherapies (Piacentini *et al.* 2014).

Treatment Duration

Social anxiety disorder is a chronic illness, and long-term treatment is generally recommended. Sutherland *et al.* (1996) reported that at 2-year follow-up, subjects who received active drug rather than placebo had improved. To date, relatively few relapse prevention studies have been done. In a 12-month trial with clonazepam, Connor *et al.* (1998) showed a 20% relapse rate for those switched to placebo compared with 0% for those who continued clonazepam. Stein *et al.* (1996) reported that 62% of subjects experienced relapse when switched double-blind from paroxetine to placebo after 12 weeks, compared with only 12% of patients whose symptoms relapsed during maintenance treatment with paroxetine. More research is needed to determine the optimal duration of medication treatment for social anxiety disorder; personalizing this dimension of care will be particularly important.

Other Issues

CBT is efficacious for social anxiety disorder and is comparable in efficacy to pharmacotherapy (Davidson *et al.* 2004b; Fedoroff and Taylor 2001), but little is known regarding whether adding CBT to medication lowers the relapse rate. In a comparative study of drug treatment and psychotherapy, Heimberg *et al.* (1998) showed that phenelzine and CBT were approximately similar, although phenelzine was more effective for patients with more severe symptoms. When subjects who had discontinued treatment were followed up, rates of relapse tended to be lower for those who had received CBT than for those who had taken phenelzine. A later study by the same group (Blanco *et al.* 2010) showed superior outcomes for combined phenelzine and CBT over each treatment given alone. Additionally, in children with anxiety disorders, including social anxiety disorder, the combination of CBT and sertraline demonstrated superior response rates compared with both monotherapies (Walkup *et al.* 2008).

Specific Phobia

Specific phobia is among the most common psychiatric disorders, with a lifetime prevalence of 8%-12.5% and a 12-month prevalence of 3.5%-9% (Alonso *et al.* 2004; Kessler *et al.* 2005a, 2005b). Although the disorder is characterized by an early onset (median age at onset = 7 years [Kessler *et al.* 2005b]), most individuals are unimpaired by their symptoms and rarely seek treatment (Magee *et al.* 1996; Stinson *et al.* 2007; Zimmerman and Mattia 2000). However, for a minority of individuals, specific phobia causes significant disability and requires treatment. The generally accepted treatment of choice is exposure therapy, which is uniformly and rapidly effective, with techniques including virtual reality as well as in vivo exposure and muscle tension exercises (for blood-injury phobia) (Canadian Psychiatric Association 2006). Few studies have evaluated the efficacy of pharmacological approaches, and no drug has yet been FDA approved for the treatment of specific phobia. No standard ratings exist for this disorder, although the Marks-Mathews Fear Questionnaire is quite suitable for blood-injury phobia and some other fears. A modification of this scale, the Marks-Sheehan Main Phobia Severity Scale (Sheehan 1986), can be recommended.

Serotonergic drugs have shown efficacy in treating symptoms of fear and avoidance in a variety of anxiety disorders and thus would seem logical choices in specific phobia. In a small 4-week double-blind controlled trial (*N* = 11), subjects receiving paroxetine ([?] 20 mg/day) had a 60% response rate compared with 17% for subjects receiving placebo (Benjamin *et al.* 2000). A randomized double-blind pilot trial compared escitalopram versus placebo over 12 weeks in 12 adults with specific phobia (Alamy *et al.* 2008). No difference in the primary outcome was observed; however, 60% of escitalopram-treated patients showed response (based on a Clinical Global Impression Scale improvement score of 1 or 2), compared with 29% of patients receiving placebo (effect size = 1.13). The findings from these two small trials require validation in larger controlled trials. In contrast, in a controlled trial of the serotonergic and noradrenergic TCA imipramine in 218 individuals with phobic disorders (agoraphobia, mixed phobia, or simple phobia) receiving 26 weeks of behavior therapy, no difference was observed between imipramine and placebo (Zitrin *et al.* 1983). The use of SSRIs for specific phobia is limited by the necessity to take these medications regularly (i.e., they are not useful prn).

In a long-term controlled study of clonazepam in DSM-III-TR (American Psychiatric Association 1987) social phobia, Davidson *et al.* (1994) observed that clonazepam was superior to placebo in reducing symptoms of anxiety related to blood-injury phobia, as measured by changes in the blood-injury phobia subscale of the Marks-Mathews Fear Questionnaire. Intermittent use of benzodiazepines also may be helpful in the acute treatment of the somatic anxiety that accompanies specific phobia, although this usage has not been an area of active investigation.

Using a novel approach, Ressler *et al.* (2004) investigated the effect of a cognitive enhancer, D-cycloserine, as an adjunct to psychotherapy. D-Cycloserine is an *N*-methyl-D-aspartate receptor partial agonist that has demonstrated improvement in extinction in rodents. Subjects with acrophobia ($n = 28$) were randomly assigned to a single dose of D-cycloserine or placebo before each of two virtual reality exposure therapy sessions. The combination of D-cycloserine and exposure therapy was associated with greater improvement in the virtual reality setting as well as on a variety of anxiety domains. These changes were noted early in treatment and were maintained at 3-month follow-up. However, other randomized controlled studies of D-cycloserine in specific phobia, including acrophobia and spider phobia, have yielded inconsistent but mostly negative findings for D-cycloserine compared with placebo (Guastella *et al.* 2007; Gutner *et al.* 2012; Kappelmann *et al.* 2020; Tart *et al.* 2013).

Generalized Anxiety Disorder

Generalized anxiety disorder is common, with a lifetime prevalence of 5%-6% (Wittchen and Hoyer 2001). In the primary care setting, it is the most prevalent anxiety disorder, with rates that exceed 8% (Goldberg and Lecrubier 1995). Generalized anxiety disorder tends to be chronic and disabling, with lifetime rates of comorbidity as high as 90% (Blanco *et al.* 2014)--particularly for depression, with a prevalence rate greater than 60%--which can increase the severity and burden of the disorder. Unlike for other anxiety disorders, the prevalence of generalized anxiety disorder tends to increase with age, with a lifetime prevalence of 11% in individuals older than 65 years and late-life onset occurring in at least 25% of cases (Zhang *et al.* 2015).

In most generalized anxiety disorder pharmacotherapy trials, the clinician-administered Hamilton Anxiety Scale (Ham-A; Hamilton 1959) has been used to assess patient symptoms. The Ham-A measures psychic and somatic symptoms of anxiety; remission is usually defined as a Ham-A score of 7 or less. The self-rated Hospital Anxiety and Depression Scale (Zigmond and Snaith 1983) is also widely used and is capable of detecting differences in treatment efficacy.

Pharmacotherapy

SSRIs and SNRIs are considered the first-line pharmacological treatment for generalized anxiety disorder. However, additional pharmacological approaches--including other antidepressants, anxiolytics, anticonvulsants, and other drugs--can also be considered. Drugs that have been approved in the United States for the treatment of generalized anxiety disorder or historical forerunners of the disorder include a large number of benzodiazepines, buspirone, immediate-release paroxetine, escitalopram, extended-release venlafaxine, and duloxetine. Pregabalin is not approved for generalized anxiety disorder in the United States but is approved for this indication in Europe. For a comparison of pharmacological treatments for generalized anxiety disorder, see the later section "Comparative Efficacy of Pharmacological, Psychological, and Combination Treatments."

Selective Serotonin Reuptake Inhibitors and Serotonin-Norepinephrine Reuptake Inhibitors

Meta-analyses have presented varying results regarding the efficacy and tolerability of each SSRI in generalized anxiety disorder. Nevertheless, within the clinical context, all SSRIs are considered to have comparable efficacy.

In one study, immediate-release paroxetine (20-50 mg/day) was as effective as imipramine and more effective than 2'-chlordesmethyldiazepam (Rocca *et al.* 1997). Compared with placebo, a similar dosage range of immediate-release paroxetine was associated with a significantly greater reduction in anxiety after 8 weeks of treatment (Pollack *et al.* 2001; Rickels *et al.* 2003), with an improvement in Ham-A-rated psychic anxiety observed as early as 1 week after treatment initiation (Pollack *et al.* 2001). Immediate-release paroxetine also improved social functioning in patients with generalized anxiety disorder (Pollack *et al.* 2001).

Escitalopram (10-20 mg/day) was superior to placebo in improving anxiety symptoms, disability, or quality of life in three 8-week trials (Davidson *et al.* 2004a; Goodman *et al.* 2005). In addition, escitalopram was equivalent to immediate-release paroxetine in a 6-month trial (Bielski *et al.* 2005). In a larger placebo-controlled trial, escitalopram (10 mg/day) was superior to paroxetine (20 mg/day), and both escitalopram dosages of 10 and 20 mg/day were superior to placebo (Baldwin *et al.* 2006). In a relapse prevention study, Allgulander *et al.* (2006) found that sustained treatment with escitalopram (20 mg/day) for up to 74 weeks reduced the relapse rate (19%) relative to placebo substitution (56%).

Sertraline was demonstrated to be superior to placebo in generalized anxiety disorder in 12-week (Allgulander *et al.* 2004a) and 10-week (Brawman-Mintzer *et al.* 2006) double-blind, placebo-controlled trials. Sertraline was well tolerated and showed beneficial effects on Ham-A-rated psychic and somatic anxiety symptoms compared with placebo (Dahl *et al.* 2005).

Several placebo-controlled trials have confirmed the short-term efficacy of extended-release venlafaxine in treating both psychic and somatic symptoms of generalized anxiety disorder over 8 weeks. In a trial of 365 adult outpatients treated with extended-release venlafaxine (75 or 150 mg/day), buspirone (30 mg/day), or placebo, mean Ham-A-adjusted scores on the anxiety and tension items were significantly more improved with both active drug dosages compared with placebo (Davidson *et al.* 1999). In addition, extended-release venlafaxine was superior to buspirone on the Hospital Anxiety and Depression Scale anxiety subscale (Davidson *et al.* 1999). In a second trial of 541 outpatients taking either extended-release venlafaxine (37.5, 75, or 150 mg/day) or placebo (Allgulander *et al.* 2001), the 75 mg/day and 150 mg/day dosages showed superior efficacy on all primary outcome measures compared with placebo (with improvement in psychic anxiety noted earlier than somatic symptoms), whereas the 37.5 mg/day dosage was superior to placebo on only one measure (the Hospital Anxiety and Depression Scale anxiety subscale). In a third trial of fixed extended-release venlafaxine (75, 150, or 225 mg/day [Rickels *et al.* 2000]), the drug was superior to placebo on all outcome measures, with the most robust effects observed at 225 mg/day. Extended-release venlafaxine significantly reduced psychic anxiety but not somatic symptoms.

Extended-release venlafaxine also has shown long-term efficacy for generalized anxiety disorder (Allgulander *et al.* 2001; Gelenberg *et al.* 2000). Additionally, extended-release venlafaxine is also effective in treating generalized anxiety disorder with comorbid depression (Silverstone and Salinas 2001). The response was delayed somewhat in subjects with comorbid generalized anxiety disorder and depression compared with those with depression alone, suggesting that individuals with comorbidity may benefit from a longer course of treatment.

Duloxetine, another SNRI antidepressant, has shown superior efficacy to placebo in generalized anxiety disorder (Allgulander *et al.* 2007; Rynn *et al.* 2008) in the dosage range of 60-120 mg/day and also seems to lessen the chance of relapse during maintenance therapy. A randomized placebo-controlled, flexible-dose study demonstrated that duloxetine was effective and well tolerated in the treatment of generalized anxiety disorder in children and adolescents ages 7-17 years (Strawn *et al.* 2015).

An interesting application of SSRIs in generalized anxiety disorder is in combination with nonbenzodiazepine hypnotics such as eszopiclone (Pollack *et al.* 2008a) and zolpidem (Fava *et al.* 2009), which may be particularly suited when insomnia is a major problem.

Anxiolytics

Benzodiazepines. Benzodiazepines have been widely used to treat acute and chronic anxiety since their introduction in the 1960s. Their activity is mediated through potentiation of the inhibitory neurotransmitter GABA at the $GABA_A$ receptor. The efficacy and relative safety of short-term benzodiazepine use (e.g., several weeks or months) is well established (Rickels *et al.* 1983; Shader and Greenblatt 1993). However, longer-term use of these drugs is more controversial and may be associated with the development of tolerance, physiological dependence, and withdrawal (if abruptly discontinued) as well as troublesome side effects including ataxia, sedation, motor dysfunction, and cognitive impairment. Furthermore, these drugs should be avoided in patients with a history of substance use disorders, and long-term use may infrequently lead to the development of major depressive disorder (Lydiard *et al.* 1987).

Benzodiazepines have been shown to be effective in generalized anxiety disorder, as reported by Rickels *et al.* (1993). The appeal of these drugs lies in their rapid onset of action, ease of use, tolerability, and relative safety. Findings from several 6-to 8-month trials of maintenance treatment for chronic anxiety have indicated continued efficacy of benzodiazepines over time (Rickels *et al.* 1983, 1988a, 1988b; Schweizer *et al.* 1993). Because generalized anxiety disorder tends to be chronic, many patients may need to continue pharmacotherapy with benzodiazepines (or other drugs) for many years, and long-term use of benzodiazepines may lead to the complications listed earlier.

Approximately 70% of patients with generalized anxiety disorder will respond to an adequate trial of a benzodiazepine (Greenblatt *et al.* 1983), which corresponds to the equivalent of a 3-to 4-week treatment course of diazepam ([?] 40 mg/day) or alprazolam (4 mg/day [Schweizer and Rickels 1996]). Discontinuation should be managed by slow taper to minimize withdrawal symptoms, rebound anxiety, and relapse potential. Some evidence suggests that benzodiazepines may be more effective in treating the autonomic arousal and somatic symptoms of generalized anxiety disorder but less effective for the psychic symptoms of worry and irritability (Rickels *et al.* 1982; Rosenbaum *et al.* 1984).

As our understanding of the phenomenology of generalized anxiety disorder has grown, there has been a greater emphasis on the psychic (e.g., worry) component of the disorder (American Psychiatric Association 2013). Given these changes, along with the high rates of comorbid depression in generalized anxiety disorder and the anxiolytic activity of many of the newer classes of antidepressants, the use of benzodiazepines as a primary treatment for generalized anxiety disorder is less recommended.

Azapirones. The azapirones are believed to exert their anxiolytic effect through partial agonism of 5-HT_{1A} receptors. A Cochrane Review of randomized controlled trials of azapirones in generalized anxiety disorder suggested that these agents are relatively well tolerated and effective, particularly for patients not previously treated with benzodiazepines (Chessick *et al.* 2006). An adequate trial of buspirone in generalized anxiety disorder would be 3-4 weeks of treatment at a dosage of up to 60 mg/day, in divided doses. Treatment-limiting effects of the drug include a greater potential for side effects at higher dosages, slower onset of action, more variable antidepressant effects, and possibly reduced effectiveness in patients with a prior favorable response to benzodiazepines (Chessick *et al.* 2006; Schweizer *et al.* 1986).

Tricyclic Antidepressants

Imipramine is recommended as a second-line pharmacological option for generalized anxiety disorder because of its adverse effects, although there is significant evidence for its benefits (Rickels and Rynn 2002).

Other Antidepressants

The antidepressant mirtazapine also has demonstrated anxiolytic properties (Ribeiro *et al.* 2001). However, published reports of its effects in generalized anxiety disorder are limited to a small open-label study in major depressive disorder and comorbid generalized anxiety disorder (Goodnick *et al.* 1999) and a small open-label generalized anxiety disorder trial in 44 outpatients (Gambi *et al.* 2005). Although the results were encouraging, data from controlled trials are needed to adequately assess a possible role for mirtazapine in generalized anxiety disorder.

In a 12-week double-blind active comparison trial of extended-release bupropion (150-300 mg/day) versus escitalopram (10-20 mg/day) in 24 subjects, Bystritsky *et al.* (2008) found similar Ham-A-rated anxiolytic efficacy for both medications.

A meta-analysis showed that vortioxetine was superior to placebo in the treatment of generalized anxiety disorder, especially for severe illness (Pae *et al.* 2015). However, a subsequent meta-analysis failed to confirm this finding (Qin *et al.* 2019). Although vortioxetine was well tolerated, it did not significantly improve response rates compared with placebo. Larger controlled trials are needed to further assess the efficacy of vortioxetine in generalized anxiety disorder.

In a meta-analysis of three randomized controlled trials, vilazodone was superior to placebo in the short-term treatment of generalized anxiety disorder (Zareifopoulos and Dylja 2017). A recent network meta-analysis also showed efficacy of vortioxetine in generalized anxiety disorder (He *et al.* 2019). However, in both analyses, vortioxetine had a higher incidence of adverse events and worse acceptability than placebo. Long-term maintenance studies are needed to evaluate the safety profile of this drug.

Pregabalin and Anticonvulsants

The a_2d calcium channel antagonist pregabalin was superior to placebo in four studies of generalized anxiety disorder (Feltner *et al.* 2003; Pande *et al.* 2003; Pohl *et al.* 2005; Rickels *et al.* 2005). Efficacy was noted early in treatment, but the ability of this drug to successfully treat some of the comorbid disorders associated with generalized anxiety disorder is unknown. A review of six short-term, double-blind, placebo-controlled pregabalin trials in generalized anxiety disorder showed that pregabalin treatment significantly improved both psychic and somatic Ham-A-rated generalized anxiety disorder symptoms, with a dose-response effect that plateaued at 300 mg/day (Lydiard *et al.* 2010). For elderly patients with generalized anxiety disorder, pregabalin has shown efficacy and reasonably good tolerability (Montgomery 2006). In a long-term trial in 624 patients with generalized anxiety disorder, responders to 8 weeks of open-label pregabalin (450 mg/day) were randomly assigned to pregabalin or placebo for 24 weeks (Feltner *et al.* 2008). Relapse rates were significantly lower for pregabalin than for placebo (42% vs. 65%), although attrition rates for pregabalin were higher (21.4% vs. 15.3%).

As noted in a case report (Markota and Morgan 2017), the clinical utility of gabapentin has been under consideration. Nevertheless, there are no published controlled studies examining the efficacy of gabapentin for generalized anxiety disorder.

The GABA reuptake inhibitor tiagabine failed to separate from placebo on key measures in three placebo-controlled multicenter trials (Pollack *et al.* 2008b).

Antipsychotics

Evidence for antipsychotic monotherapy in generalized anxiety disorder is limited for some agents and more robust for others. Currently, the strongest evidence supporting atypical antipsychotic use in generalized anxiety disorder is for extended-release quetiapine. This agent was shown to be effective and superior to placebo in a multicenter trial, and a dosage of 150 mg/day was effective for both psychic and somatic anxiety symptoms, with improvement being noted as early as 4 days after initiation of treatment (Bandelow *et al.* 2010). Another 8-week randomized controlled trial also demonstrated the efficacy of extended-release quetiapine (150 and 300 mg/day) in generalized anxiety disorder (Merideth *et al.* 2012). In a longer-term double-blind, placebo-controlled multicenter maintenance trial, extended-release quetiapine (50-300 mg/day) was effective in preventing the recurrence of anxiety symptoms (Katzman *et al.* 2011).

Antipsychotics have also been examined as augmentation options for patients with treatment-resistant generalized anxiety disorder who show a less-than-adequate response to antidepressants or anxiolytics. In a 5-week, double-blind, placebo-controlled trial, low-dose adjunctive risperidone was effective in reducing Ham-A scores (Brawman-Mintzer *et al.* 2005). Aripiprazole augmentation for treatment-resistant generalized anxiety disorder also showed promising results in two small open-label 6-to 8-week trials (Hoge *et al.* 2008; Menza *et al.* 2007). One 6-week randomized placebo-controlled study showed that olanzapine augmentation resulted in a greater proportion of responders with treatment-resistant generalized anxiety disorder, although there were no statistically significant differences from placebo in Ham-A scores (Pollack *et al.* 2006). Whereas one 8-week randomized placebo-controlled trial (not double-blind) demonstrated efficacy of quetiapine augmentation (Altamura *et al.* 2011), two 8-week double-blind, randomized placebo-controlled trials with larger samples did not report efficacy (Khan *et al.* 2013; Simon *et al.* 2008). A randomized placebo-controlled trial did not report efficacy of ziprasidone in treatment-resistant generalized anxiety disorder (Lohoff *et al.* 2010).

Long-term use of atypical antipsychotics carries concerns about tolerability and safety, especially in regard to weight gain and metabolic adverse effects. These concerns must be balanced against the long-term benefits of their use for generalized anxiety disorder in terms of reduced disability and improved functionality.

Hydroxyzine

Hydroxyzine blocks histamine$_1$ and muscarinic receptors. In three controlled trials, hydroxyzine was superior to placebo (Ferreri and Hantouche 1998; Lader and Scotto 1998; Llorca *et al.* 2002). In a Cochrane Review comparing hydroxyzine with other anxiolytic agents such as benzodiazepines and buspirone, hydroxyzine was equivalent in tolerability, efficacy, and acceptability for the treatment of generalized anxiety disorder (Guaiana *et al.* 2010). In Europe, previous reports of hydroxyzine-related ventricular arrhythmias led to cautionary labeling regarding the use of hydroxyzine, and the maximum dosage for this drug is restricted to 100 mg/day (European Medicines Agency 2015).

Other Drugs

Riluzole, a presynaptic glutamate release inhibitor, showed promise in a small open-label study at a dosage of 100 mg/day (Mathew *et al.* 2005) but has not been studied in placebo-controlled, double-blind studies.

Agomelatine, a 5-HT$_{2C}$ receptor antagonist and melatonin$_{1/2}$ receptor agonist, was efficacious in the short-term treatment of generalized anxiety disorder (Stein *et al.* 2014, 2008) and was effective and well tolerated in longer-term treatment (Stein *et al.* 2012). This drug is not available in the United States.

Complementary Treatments

Complementary treatments have had mixed results for generalized anxiety disorder. Homeopathy was ineffective in one trial (Bonne *et al.* 2003). The herbal remedy kava did not separate from placebo in one trial (Connor and Davidson 2002), although Sarris *et al.* (2009) showed some evidence supporting the benefit of a water-soluble formulation of kava in subjects with short-term generalized anxiety disorder-like symptoms. Liver damage remains a potentially devastating concern, however, and even the preferred aqueous extract cannot be regarded as entirely safe, particularly at kava dosages greater than 250 mg/day (Teschke and Schulze 2010). Two small placebo-controlled

trials suggested that chamomile and Ginkgo biloba may have modest anxiolytic effects in patients with mild to moderate generalized anxiety disorder (Amsterdam *et al.* 2009; Woelk *et al.* 2007). Kasper *et al.* (2014) demonstrated that lavender oil extract at dosages of 80 and 160 mg/day was superior to placebo and was better tolerated than paroxetine in a four-arm trial of patients with DSM-5 generalized anxiety disorder. Later studies by these researchers showed that the compound reduced 5-HT$_{1A}$ receptor binding in the hippocampus, anterior cingulate cortex, and fusiform and temporal gyri (Baldinger *et al.* 2014).

Comparative Efficacy of Pharmacological, Psychological, and Combination Treatments

In a meta-analysis of generalized anxiety disorder studies, Hidalgo *et al.* (2007) reported effect sizes for each drug or drug group versus placebo. These effect sizes were as follows (in diminishing order from largest to smallest): pregabalin, 0.50; hydroxyzine, 0.45; extended-release venlafaxine, 0.42; benzodiazepines, 0.38; SSRIs, 0.36; buspirone, 0.17; and homeopathy and herbal treatment, [?] 0.31. In another meta-analysis, it was uncertain whether antidepressant drugs, benzodiazepines, and pregabalin differed in their relative efficacy in reducing the severity of psychic or somatic anxiety symptoms in generalized anxiety disorder (Baldwin *et al.* 2011). A more recent network meta-analysis showed that duloxetine, venlafaxine, escitalopram, and pregabalin were more efficacious than placebo, with relatively good acceptability (Slee *et al.* 2019). Mirtazapine, sertraline, fluoxetine, buspirone, and agomelatine were also efficacious and well tolerated, but these findings were limited by small sample sizes. Quetiapine, paroxetine, and benzodiazepines were effective but poorly tolerated compared with placebo. Among these agents, quetiapine had the largest effect on Ham-A scores (Slee *et al.* 2019). In another network meta-analysis that compared SSRIs, SNRIs, and newer antidepressants (vilazodone, levomilnacipran, and vortioxetine), all of the drugs except fluoxetine and vortioxetine were more effective than placebo, with duloxetine and escitalopram showing the greatest efficacy among these (He *et al.* 2019).

Medications that have been approved in the United States for the treatment of generalized anxiety disorder or historical forerunners of the disorder include a large number of benzodiazepines, buspirone, immediate-release paroxetine, escitalopram, extended-release venlafaxine, and duloxetine. Pregabalin is not approved for treatment of generalized anxiety disorder in the United States but is approved for this indication in Europe.

There is also convincing evidence in favor of efficacy for CBT in generalized anxiety disorder, with sustained benefit over 2 years of follow-up (for a review, see Canadian Psychiatric Association 2006). A Cochrane Review reported that CBT was more effective in reducing anxiety symptoms in short-term treatment of generalized anxiety disorder compared with treatment as usual or waiting-list control conditions (Hunot *et al.* 2007). There are no randomized controlled studies that compare, or combine, CBT and pharmacotherapy in generalized anxiety disorder

(Bandelow *et al.* 2007). On pragmatic grounds, one may consider their combination for patients whose symptoms have shown only a partial response to a thorough course of either CBT or medication alone.

Conclusion

The SSRIs, all of which were initially introduced for depression, have established primacy in the treatment of most major anxiety (or anxiety-related) disorders. Their position is based on numerous placebo-controlled trials, and they are considered first-line drugs for the treatment of these disorders, followed closely by the SNRIs. There is evidence that these drugs also offer some protection against relapse. However, they are not 100% efficacious, they carry some limiting side effects, and they may require supplementation with (or substitution of) drugs from other categories. We have reviewed the main clinical trials of these other drugs and expect further progress--with both established drugs and novel categories--in the pharmacotherapy of anxiety and related disorders. Among many unexplored areas, we need to know more about the treatment of resistant and comorbid anxiety disorders, combined psychotherapy and pharmacotherapy interventions, comparative efficacy of pharmacotherapy and psychosocial treatments, and possible early interventions that may help prevent and/or alleviate the severity and chronicity of these conditions.

This chapter is an update and revision of David D, Davidson JRT: "Treatment of Anxiety and Related Disorders," in *The American Psychiatric Association Publishing Textbook of Psychopharmacology*, 5th Edition. Edited by Schatzberg AF, Nemeroff CB. Washington, DC, American Psychiatric Publishing, 2017, pp. 1195-1239.

CHAPTER 51

Treatment of Posttraumatic Stress Disorder

Charles B. Nemeroff, M.D., Ph.D.

Valerie Rosen, M.D.

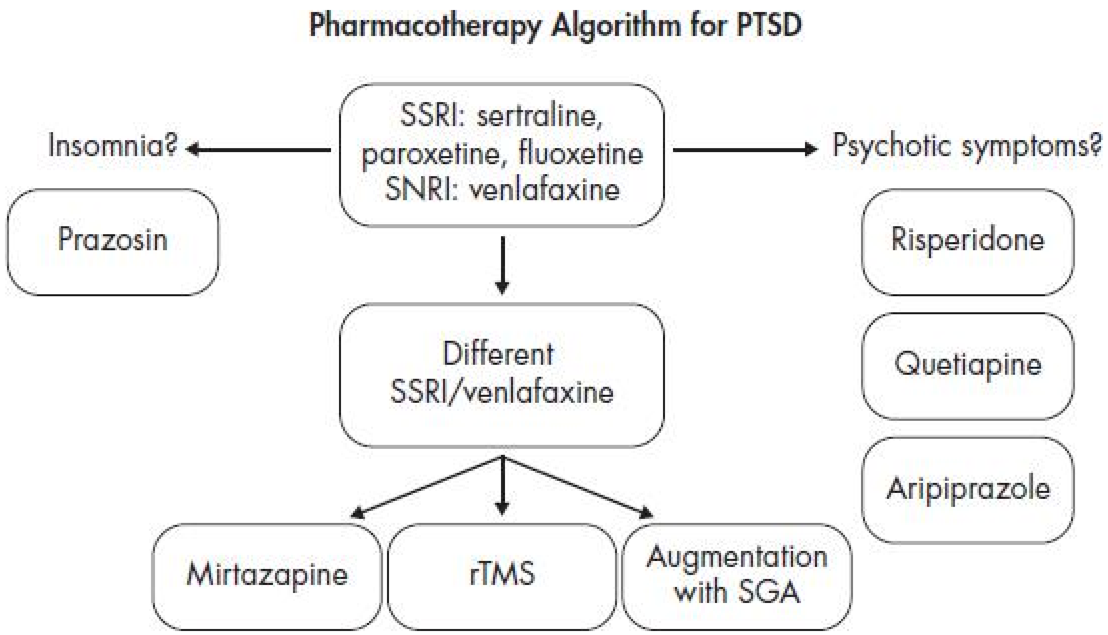
Nicholas F. Ortiz, M.D.

After they endure a trauma, most individuals will experience a temporary increase in anxiety, dysphoria, and insomnia. For the majority, an adaptive fear-extinction process will occur over time, leading to a reduction in inappropriate reactive symptoms while still allowing improved discernment of future threats. For others, however, the ability to discern threats or inhibit fear responses elicited from neutral stimuli remains impaired following trauma and results in intrusive and distressing thoughts, avoidance of potential triggers, heightened vigilance to potential threats, and depressed mood.

Most individuals will experience a traumatic event in their lifetime. In a 2016 survey, approximately 70% of respondents reported at least one traumatic event occurring in their life. In the United States, the estimated lifetime prevalence of PTSD is 4%-8% and is higher for younger, white, female, and Native American populations (Goldstein *et al.* 2016). Among individuals with PTSD, experiencing sexual violence before age 18 years and seeing a dead body or body parts were the most common forms of trauma exposure reported (Goldstein *et al.* 2016). Alcohol and drug use disorders are highly comorbid in the PTSD population, with estimates suggesting that as many as 52% of men and 28% of women with PTSD will meet criteria for an alcohol use disorder and that 35% of men and 27% of women with PTSD will meet criteria for a drug use disorder at some point in their lives (Kessler *et al.* 1995). Similarly, depression is highly prevalent and comorbid in this population, and it is estimated that as many as half of individuals with PTSD also meet criteria for major depressive disorder (MDD) during their illness (Rosen *et al.* 2020).

Current recommendations for individuals with PTSD indicate trauma-focused psychotherapy (e.g., cognitive processing therapy, prolonged exposure, etc.) as a first-line treatment. Despite the relative success of these treatments, up to 50% of individuals with PTSD will continue to experience refractory symptoms (Bradley *et al.* 2005). The FDA approved sertraline and paroxetine for the treatment of PTSD in 1999 and 2001, respectively; however, no additional medications for PTSD have been approved to date.

Current pharmacotherapy guidelines recommend choosing a selective serotonin reuptake inhibitor (SSRI; e.g., paroxetine, sertraline, or fluoxetine) as the first-line treatment for PTSD. If PTSD symptoms are still prominent, a different SSRI or a serotonin-norepinephrine reuptake inhibitor (SNRI; e.g., venlafaxine) should be considered. If the individual has comorbid psychotic symptoms, an atypical antipsychotic such as risperidone or quetiapine should be added. If the individual has insomnia or nightmares associated with PTSD, prazosin or trazodone might be considered; however, the evidence base here is relatively weak, as described later in this chapter. Benzodiazepines and cannabis should be avoided in individuals with PTSD because they can perpetuate avoidance. Mood-stabilizing medications have demonstrated only a modest effect on PTSD symptoms at best and should only be used for patients with comorbid bipolar disorder. Several atypical antipsychotics have demonstrated meaningful effects on symptom clusters but must be weighed with consideration of their potential metabolic consequences. Newer areas of investigational therapy include repetitive transcranial magnetic stimulation (rTMS) and other neuromodulation modalities, 3,4-methylenedioxymethamphetamine (MDMA)-assisted psychotherapy, esketamine, and psilocybin. Figure 51-1 provides a brief summary of evidence-based somatic therapies for PTSD.



Pharmacotherapy Algorithm for PTSD
SSRI: sertraline, paroxetine, fluoxetine SNRI: venlafaxine
Insomnia?
Prazosin
Psychotic symptoms?
Risperidone
Quetiapine
Aripiprazole
Different SSRI/venlafaxine
Mirtazapine
rTMS
Augmentation with SGA

FIGURE 51-1. Pharmacotherapy algorithm for posttraumatic stress disorder.

rTMS = repetitive transcranial magnetic stimulation; SGA = second-generation antipsychotic; SNRI = serotonin-norepinephrine reuptake inhibitor; SSRI = selective serotonin reuptake inhibitor.

Antidepressants

Selective Serotonin Reuptake Inhibitors

Only two medications are FDA approved for PTSD: sertraline and paroxetine. These medications, in addition to other SSRIs, are often used as first-line agents to treat PTSD (Mohamed and Rosenheck 2008). Current treatment guidelines from the U.S. Department of Veterans Affairs and Department of Defense (2017) and the U.K. National Institute for Health and Care Excellence (2018) all recommend SSRIs, in addition to the SNRI venlafaxine, as first-line pharmacotherapy treatments for PTSD. Overall, the estimated impact of these medications on PTSD symptoms is modest, with effect sizes (Cohen's *d*) of 0.38 for paroxetine, 0.32 for venlafaxine, 0.30 for fluoxetine, and 0.24 for sertraline (Cipriani *et al.* 2018). In two studies, investigators found no difference between SSRI treatment groups and placebo for PTSD (Hertzberg *et al.* 2000; Martenyi *et al.* 2007). Placebo-controlled studies investigating treatments for PTSD, including those in veteran populations, demonstrate very large placebo responses that often influence the detectability of a significant difference between treatment groups (Bisson *et al.* 2020; Mohamed and Rosenheck 2008). In patients with comorbidity associated with PTSD (most commonly MDD [40%-50%]), the relative effect of these medications increased (Rosen *et al.* 2020). It remains to be determined whether there is a true class effect from SSRIs or if only a select few possess clinical efficacy.

Paroxetine

Several large placebo-controlled investigations have shown paroxetine to be significantly superior to placebo for treating PTSD in diverse populations. In a 12-week placebo-controlled study involving 551 patients with PTSD, Marshall *et al.* (2001) found significantly greater reductions in PTSD symptoms (as assessed with the Clinician-Administered PTSD Scale [CAPS]), as well as in depressive symptoms, for participants receiving paroxetine compared with those receiving placebo. Side effects of paroxetine were not significantly different between groups (Marshall *et al.* 2001). In another placebo-controlled study with 307 participants (n = 156 and n = 151 in the placebo and the treatment groups, respectively), Tucker *et al.* (2001) showed significant reductions in PTSD symptoms (measured with the CAPS) and also found paroxetine to be well tolerated. A placebo-controlled trial using flexible dosing of paroxetine showed significant reductions in CAPS scores and depressive symptoms and reduced dissociation at 12 weeks of treatment (Marshall *et al.* 2007). Several open-label studies including international data from Japan and Bosnia have also shown similar reductions in PTSD symptoms in individuals treated with paroxetine (Kim *et al.* 2008; Kucukalic *et al.* 2008; Marshall *et al.* 1998).

Sertraline

Sertraline has also shown superiority compared with placebo for the treatment of PTSD in several randomized double-blind trials (Brady *et al.* 2000; Davidson *et al.* 2001; Stein *et al.* 2006). One study with 200 subjects found sertraline to be superior to placebo for reducing all symptom clusters of PTSD; however, sertraline was associated with higher rates of side effects, including diarrhea, nausea, insomnia, and fatigue (Davidson *et al.* 2001). In another study evaluating 187 participants with PTSD using flexible dosing of sertraline (50-200 mg/day), investigators reported a significantly greater reduction in the PTSD symptom clusters of hypervigilance and avoidance but not in intrusion symptoms (Brady *et al.* 2000). Insomnia was statistically more common in the treatment group than in the placebo group (Brady *et al.* 2000). Stein *et al.* (2006) conducted a double-blind, placebo-controlled study with 395 individuals with PTSD secondary to interpersonal trauma or child abuse. The authors found flexible dosing of sertraline (50-200 mg/day) to be statistically superior to placebo in the reduction of trauma symptoms (measured via CAPS scores), irrespective of the nature of the index trauma (Stein *et al.* 2006).

In other studies involving male combat veterans, investigators have not found statistical differences in PTSD symptom reduction between placebo and sertraline treatment groups. In a 12-week double-blind, placebo-controlled study in 169 male Vietnam veterans with PTSD, no difference in PTSD symptom reduction was detected between groups; 13% of sertraline-treated patients dropped out before study end as a result of side effects (Friedman *et al.* 2007). In another double-blind, placebo-controlled study evaluating 42 Israeli military veterans, investigators found no statistical difference in PTSD symptom reduction between groups after 10 weeks (Zohar *et al.* 2002). In both of these studies, the placebo response rate was substantial.

Overall, sertraline has demonstrated effectiveness in reducing PTSD symptoms in placebo-controlled trials. However, the effect size is smaller than those for other evidence-based therapies.

Fluoxetine

Although fluoxetine is not FDA approved for PTSD, several placebo-controlled trials have shown this agent to be an effective treatment option for individuals with the disorder (Connor *et al.* 1999; Martenyi and Soldatenkova 2006; Martenyi *et al.* 2002; van der Kolk *et al.* 1994, 2007). In one such study with 301 participants from war-torn regions of Israel, Europe, and South Africa, treatment with fluoxetine was associated with significant reductions in CAPS, Treatment-Outcome PTSD Scale (TOP-8), Montgomery-Asberg Depression Rating Scale (MADRS), and Hamilton Anxiety Scale (Ham-A) scores after 12 weeks. Fluoxetine was well tolerated, with a mean dosage of 57 mg/day used during the study (Martenyi *et al.* 2002). Another 5-week randomized placebo-controlled trial with 64 participants (approximately half of whom were veterans) reported significant reductions in PTSD symptoms measured by CAPS scores in nonveterans with PTSD; however, this effect was significantly diminished in the veteran subgroup (van der Kolk *et al.* 1994). Connor *et al.* (1999) conducted a double-blind, placebo-controlled trial in 53 civilian patients and found significant reductions in PTSD symptoms measured by patient and clinician rating scales at 12 weeks. Finally, another study evaluated flexible dosing of fluoxetine (20-80 mg/day) in 144 predominantly male veterans from Yugoslavia, Croatia, and Bosnia and Herzegovina (Martenyi and Soldatenkova 2006). Participants showed improvement in CAPS and TOP-8 scores after 12 weeks, and there was a significantly greater risk of relapse in the placebo group compared with the fluoxetine group at 24 weeks (Martenyi and Soldatenkova 2006).

As noted earlier, several studies have reported no statistical differences in PTSD symptom reduction with fluoxetine treatment. A recent multisite, double-blind, placebo-controlled trial of 441 predominantly female individuals assigned to a fixed dosage of fluoxetine (20 or 40 mg/day) or placebo reported no drug-related reduction in PTSD symptoms (measured with the CAPS) after 12 weeks of treatment (Martenyi *et al.* 2007). Unfortunately, there was a large placebo response rate (37%) comparable to that of fluoxetine (43% [Martenyi *et al.* 2007]). Similarly, investigators in a small placebo-controlled study of 12 male veterans with PTSD found no difference between groups in PTSD symptom reduction after 12 weeks (Hertzberg *et al.* 2000). Based on the available data, fluoxetine seems to have moderate efficacy in reducing PTSD symptoms and is well tolerated overall.

Citalopram and Escitalopram

Compared with the aforementioned SSRIs, fewer studies have examined the effect of citalopram and escitalopram on PTSD symptom reduction. In a 12-week open-label trial examining high-dosage citalopram (40 mg/day by 4 weeks) in 45 individuals with PTSD, researchers found significant reductions in CAPS scores at 3-and 6-month follow-up assessments (Qi *et al.* 2017). In another open-label trial evaluating 25 military veterans with PTSD, investigators found that fixed-dosage escitalopram (10 mg/day for 4 weeks, then 20 mg/day until study completion) resulted in significant reductions in CAPS scores in all domains, with specific improvement noted on the hyperarousal and avoidance subscales (Robert *et al.* 2006). Another open trial of citalopram in 14 adults with PTSD reported significant reductions in core symptoms of PTSD (measured via the CAPS) after 8 weeks (Seedat *et al.* 2000). However, in a comparison of sertraline ($n = 23$), citalopram ($n = 25$), and placebo ($n = 10$) for the treatment of PTSD, reductions in PTSD symptoms were observed in all three groups but were statistically significant only in the sertraline group (Tucker *et al.* 2003).

Other Antidepressants

Venlafaxine

The SNRI venlafaxine is an effective treatment for PTSD. In a large multicenter study, Davidson *et al.* (2006a) evaluated treatment responses in 538 outpatients with PTSD randomly assigned to flexibly dosed extended-release venlafaxine (mean = 225 mg/day), sertraline (mean = 151 mg/day), or placebo. At 12 weeks, the venlafaxine group demonstrated a significantly greater reduction in PTSD symptoms (measured via CAPS scores) compared with sertraline or placebo. The venlafaxine group also had the highest remission rate (30.2%; $P < 0.05$) compared with the groups treated with sertraline (24.3%) or placebo (19.6%); both venlafaxine and sertraline were well tolerated (Davidson *et al.* 2006a). Another large placebo-controlled study compared extended-release venlafaxine with placebo in adult outpatients (*N* = 329) with chronic PTSD (Davidson *et al.* 2006b). A mean dosage of extended-release venlafaxine of 221.5 mg/day was associated with significantly greater reductions in PTSD symptoms measured with CAPS scores (-51.7 for extended-release venlafaxine vs. -43.9 for placebo; *P* = 0.006) and significantly higher rates of remission (50.9% for extended-release venlafaxine vs. 37.5% for placebo; *P* = 0.01) after 24 weeks of treatment. Dropout rates did not differ between groups, and extended-release venlafaxine was well tolerated (Davidson *et al.* 2006b).

Mirtazapine

Mirtazapine is an atypical antidepressant with a unique pharmacological profile that has shown initial promise for treating individuals with PTSD. In a randomized open-label trial comparing mirtazapine and sertraline (mean dosage = 34.1 mg/day and 101.5 mg/day, respectively) in 100 Korean veterans with PTSD, researchers found that the mirtazapine-treated group had a greater reduction in CAPS scores compared with the sertraline-treated group; this difference attained statistical significance at 6 weeks. In this study, treatment with mirtazapine was associated with dry mouth and constipation in approximately 20% of individuals, whereas treatment with sertraline was associated with indigestion in 14% (Chung *et al.* 2004). Another open-label study in 13 individuals with combat-related PTSD found a CAPS reduction from a mean pretreatment score of 87.5 to 64.4 (*P* = 0.01) after 12 weeks of mirtazapine treatment (Alderman *et al.* 2009). A randomized placebo-controlled trial of 29 individuals with PTSD found improvements in Short PostTraumatic Stress Disorder Rating Interview scores after 8 weeks, and another continuation study found statistically significant reductions in scores after 24 weeks, with few dropouts related to a side-effect burden (Davidson *et al.* 2003; Kim *et al.* 2005). A 2020 placebo-controlled study with an initial 8-week double-blind phase followed by an 8-week open-label phase was conducted in 78 U.S. veterans with PTSD (Davis *et al.* 2020). The investigators found no statistically significant effect in the primary outcome measure, Structured Interview for PTSD (SIP) scores. The reduction in CAPS scores was significant in the open-label phase, and there were no significant differences in the occurrence of adverse events (Davis *et al.* 2020). Finally, a study evaluating the addition of mirtazapine to ongoing sertraline therapy for PTSD in a civilian and majority female population reported that compared with placebo, adjunctive mirtazapine treatment was associated with a greater reduction in CAPS scores and depression scales, although this difference was not statistically significant at 24 weeks (Schneier *et al.* 2015). Treatment with mirtazapine should be considered for patients with PTSD who could not tolerate or whose symptoms failed to respond to previous treatment with an SSRI (e.g., paroxetine, fluoxetine, or sertraline) or venlafaxine.

Vortioxetine

Vortioxetine is a multimodal serotonin modulator that was recently investigated in a flexible-dosage (10-20 mg/day), placebo-controlled trial in 41 individuals with PTSD. At the end of 12 weeks, vortioxetine did not separate from placebo in reducing Clinician-Administered PTSD Scale for DSM-5 (CAPS-5) scores (Dunlop *et al.* 2021).

Duloxetine

No placebo-controlled or blinded studies investigating the effect of duloxetine in PTSD were identified in this review. One small naturalistic study of 20 male white Vietnam veterans reported that treatment with duloxetine (60-120 mg/day) was associated with significant reductions in PTSD and depressive symptoms after 8 weeks (Walderhaug *et al.* 2010).

Bupropion

In one small open-label study of 17 individuals, bupropion reduced hyperarousal symptoms of PTSD and depressive symptoms after 6 weeks (Canive *et al.* 1998). Bupropion was started at 75 mg bid and increased to 150 mg bid after 2 weeks, with a maximum allowable dosage of 200 mg bid. A larger placebo-controlled trial of 30 individuals reported no difference in the reduction of PTSD symptoms between sustained-release bupropion and placebo after 8 weeks (Becker *et al.* 2007). In this study, participants were randomly assigned (2:1) to double-blind treatment with sustained-release bupropion or placebo. Sustained-release bupropion was started at 100 mg every morning for 2 weeks and titrated up to 150 mg bid by week 4 if no significant improvement was shown (Becker *et al.* 2007).

Monoamine Oxidase Inhibitors and Tricyclic Antidepressants

In an 8-week placebo-controlled study of 62 veterans with PTSD comparing phenelzine (a monoamine oxidase inhibitor) and imipramine (a tricyclic antidepressant), both treatment groups demonstrated significant reductions in Clinical Global Impression Scale scores compared with placebo. However, reductions were greater in the phenelzine group and were even more pronounced when measured via the Impact of Event Scale (Frank *et al.* 1988). Another 8-week placebo-controlled trial comparing phenelzine, imipramine, and placebo in 60 male veterans with PTSD reported that by week 5, both treatment groups had experienced significant symptom reduction (measured using the Impact of Event Scale), with 44% improvement in the phenelzine group and 25% improvement in the imipramine group. The phenelzine group had a higher dropout rate as a result of side effects compared with the imipramine group (17% vs. 5%, respectively [Kosten *et al.* 1991]). Desipramine was not found to improve PTSD symptoms after 4 weeks in one small study of 18 war veterans (Reist *et al.* 1989). Amitriptyline was investigated in an 8-week flexible-dosage, placebo-controlled study in 46 veterans with PTSD. For individuals who completed 8 weeks of treatment ($n = 33$), there were significant reductions in scores on the Impact of Event Scale and the Hamilton Rating Scale for Depression (Ham-D); however, 64% still met criteria for PTSD (Davidson *et al.* 1990).

Evidence-Based Psychotherapy Combined With Antidepressants

A 2010 Cochrane Review evaluated four trials of combined medication and psychotherapy for PTSD. The authors concluded that there was no evidence that the combination was superior to either therapy or medication alone (Hetrick *et al.* 2010). After 10 weeks of sertraline treatment (mean dosage = 173 mg/day), patients in an augmentation strategy study were randomly assigned to either 5 additional weeks of sertraline monotherapy or sertraline plus 10 sessions of prolonged exposure over 5 weeks. Significant improvement in PTSD symptom severity stopped after 10 weeks in the medication-only group, whereas partial responders to sertraline showed further reduction in PTSD severity in the prolonged exposure augmentation group; however, the differences were not statistically significant (Rothbaum *et al.* 2006). In the Prolonged Exposure and Sertraline Trial (PROGrESS), a randomized controlled trial (RCT) of veterans with combat-related PTSD (Rauch *et al.* 2019), participants were randomly assigned to prolonged exposure therapy plus placebo, prolonged exposure therapy plus sertraline hydrochloride, or sertraline plus enhanced medication management and were followed for 24 weeks. Although all groups experienced significant reductions in PTSD symptoms, there were no significant between-group differences (Rauch *et al.* 2019). In a re-examination of PROGrESS participants who completed outcome measures after treatment, no significant differences were noted between groups in terms of residual symptoms (Tripp *et al.* 2020).

Schneier *et al.* (2012) conducted a small RCT of 37 survivors of the World Trade Center attack on September 11, 2001, with PTSD. Participants who received prolonged exposure plus controlled-release paroxetine (mean = 32.2 mg/day) versus prolonged exposure plus placebo demonstrated significantly greater improvement in PTSD symptoms, quality of life, and remission rates (8 of 19 [42.1%] with combined treatment vs. 3 of 18 [16.7%] for prolonged exposure plus placebo (Schneier *et al.* 2012). In

Poland, Popiel *et al.* (2015) conducted an RCT with 227 patients who developed PTSD after a motor vehicle accident. In terms of remission rates, prolonged exposure was superior to paroxetine and the combination of the two was not better than either alone (Popiel *et al.* 2015).

Antipsychotics

Atypical antipsychotics have pharmacological properties that may benefit individuals with PTSD, including histamine receptor antagonism, serotonin$_2$ receptor antagonism, and dopamine receptor antagonism that impact insomnia, mood dysregulation, and symptoms of hyperarousal, paranoia, and psychosis. These medications are often considered for patients with PTSD whose symptoms do not respond to initial treatment with antidepressant medications and especially for individuals with psychotic symptoms (Compean and Hamner 2019).

Risperidone

In 1994, the FDA approved risperidone for the treatment of schizophrenia. This agent has since become widely used by clinicians for a variety of psychiatric disorders, including bipolar disorder and treatment-resistant depression. Risperidone has been extensively evaluated as an augmentation agent and as a monotherapy option for PTSD.

Risperidone augmentation of current SSRI therapy has been examined in individuals with civilian and service-related PTSD. Krystal *et al.* (2011) conducted a 6-month double-blind, randomized placebo-controlled trial with 296 military veterans with service-related PTSD treated with risperidone 3 mg/day. Study participants were mostly male Vietnam veterans with severe PTSD symptoms, often with comorbid depression, and a low prevalence rate of psychotic symptoms. Individuals who received adjunctive treatment with risperidone did not demonstrate statistically significant improvement in total CAPS, global assessment (Clinical Global Impression Scale total), or quality of life (36-Item Short-Form Health Survey V) scores (Krystal *et al.* 2011).

Bartzokis *et al.* (2005) evaluated 65 male veterans with severe PTSD (CAPS score = 100, on average) in a residential treatment program for 1 month and subsequently followed them for 3 months. These participants had stable disease with a psychopharmacological regimen and were further randomly assigned to placebo or adjunctive risperidone (3 mg/day, on average). Of the 48 patients who completed the study, both groups demonstrated improvements in CAPS scores during the first month; however, only the risperidone group demonstrated a significant improvement in total CAPS scores at the study endpoint. Bartzokis *et al.* (2005) also found significant improvements in Ham-A and Positive and Negative Syndrome Scale (PANSS) scores in the adjunctive risperidone treatment group.

Rothbaum *et al.* (2008) evaluated adjunctive risperidone in a civilian PTSD population treated with sertraline. In this study, male and female participants with a CAPS score greater than 50 were treated with an open-label trial of sertraline for 8 weeks. Individuals whose symptoms did not remit (as evidenced by failure to reach a 70% reduction in CAPS scores) continued sertraline and were randomly assigned to adjunctive risperidone (2.1 mg/day, on average) or placebo. Of the 20 patients who completed Phase II of this study, there were no appreciable differences in CAPS score changes between the placebo and adjunctive risperidone groups. CAPS scores decreased by a mean 28.5 points in Phase I, followed by a placebo response that paralleled that in the adjunctive risperidone group (mean score reduction = 23.1 and 23.5 points, respectively). There were trends toward improvements in sleep quality (but not in nightmare frequency) and PANSS positive symptom subscale scores in the adjunctive risperidone group, but these results were not statistically significant.

In a study by Reich *et al.* (2004), 21 women with PTSD related to childhood physical, sexual, emotional, and verbal abuse who were in stable maintenance treatment with one antidepressant and/or one hypnotic medication were randomly assigned to adjunctive risperidone (mean dosage = 1.4 mg/day) or placebo for 8 weeks. The group receiving adjunctive risperidone (n = 9) demonstrated a significant reduction in CAPS total scores (mean = -2.74) in addition to significant reductions in CAPS hyperarousal and intrusive subscale scores.

Risperidone has also been examined in the treatment of individuals with PTSD and co-occurring psychotic symptoms. Hamner *et al.* (2003b) examined the potential efficacy of adjunctive risperidone versus placebo in 40 combat veterans with chronic PTSD with comorbid psychotic features, defined as occurrences outside flashbacks or reexperiencing episodes, with a PANSS score of 60 or higher. Participants were maintained on their previous psychotropic medications but had to have a constant medication regimen for 1 month before starting the study. The average risperidone dosage was 2.5 mg/day. All participants exhibited a significant reduction in PANSS total scores; however, the decrease in CAPS scores, present in both the risperidone and the placebo groups, did not differ statistically (Hamner *et al.* 2003b). Pivac and Kozaric-Kovacic (2006) similarly investigated risperidone as monotherapy in 26 Croatian combat veterans with PTSD who also reported hallucinations or delusions. A mean risperidone dosage of 3.6 mg/day resulted in a significant improvement in both PANSS and PTSD-Interview scores (Pivac and Kozaric-Kovacic 2006). Thus, risperidone is a rational treatment option for individuals with PTSD and co-occurring psychotic symptoms.

Quetiapine

Quetiapine is an atypical antipsychotic approved by the FDA for schizophrenia, bipolar disorder, and bipolar depression. Quetiapine is a partial agonist of the serotonin$_{1A}$ receptor and an antagonist at serotonin$_{2A}$ and dopamine$_2$ receptors, a$_1$ and a$_2$ adrenergic receptors, and histamine$_1$ receptors. The main metabolite of quetiapine, norquetiapine, is also a norepinephrine reuptake inhibitor. This pharmacological profile may afford quetiapine an advantage over other atypical antipsychotics for the treatment of PTSD.

Quetiapine has been evaluated as a monotherapy and as an adjunctive treatment to SSRIs for individuals with PTSD. Villarreal *et al.* (2016) conducted a 12-week randomized placebo-controlled trial of 80 individuals with PTSD and evaluated the effectiveness of quetiapine monotherapy using CAPS scores as the primary outcome measure. The mean quetiapine dosage used was 258 mg/day. Quetiapine-treated participants exhibited a significantly greater reduction in overall CAPS scores as well as significantly greater reductions in CAPS subscale scores for reexperiencing and hyperarousal symptoms compared with the placebo group. Patients in the treatment group were also observed to have significant reductions in PANSS, Ham-A, and Ham-D scores.

As an adjunctive treatment to SSRI therapy, quetiapine was also shown to improve CAPS subscale and PANSS scores in a small 6-week open-label trial with 20 participants (Hamner *et al.* 2003a). Ahearn *et al.* (2006) also investigated adjunctive quetiapine in 15 patients over an 8-week period (mean quetiapine dosage = 216 mg/day) and found a 40% reduction in overall CAPS scores, with significant reductions in all subscale scores.

Quetiapine has demonstrated efficacy in randomized placebo-controlled trials and thus deserves consideration as a monotherapy for individuals whose symptoms do not respond to SSRI treatment, as an adjunctive agent, and as a treatment option for individuals experiencing psychotic symptoms associated with their PTSD. Quetiapine is associated with weight gain and elevation of plasma lipids, especially triglycerides. Careful consideration should be taken before initiating quetiapine because these side effects in combination with smoking, which is prevalent in this population, can have additive effects on cardiovascular risk.

Olanzapine

Olanzapine, which shares similarities in its pharmacological profile with that of quetiapine, has also been posited to have a role in the treatment of individuals with PTSD. Several large randomized placebo-controlled studies evaluating olanzapine as a monotherapy and as an adjunctive agent have been conducted. Butterfield *et al.* (2001) performed a 10-week double-blind, placebo-controlled study with a mean olanzapine dosage of 14.1 mg/day for 15 patients with PTSD. There were no observed differences in TOP-8 scores between groups at study end (Butterfield *et al.* 2001). In contrast, Carey *et al.* (2012) conducted a similar 8-week double-blind, placebo-controlled study of olanzapine monotherapy for the treatment of PTSD. Statistically significant improvements in CAPS avoidance and numbing subscale scores, but not in overall CAPS scores, were observed.

Stein *et al.* (2002) evaluated adjunctive olanzapine treatment for SSRI-resistant combat-related PTSD. There was a statistically significantly greater reduction in CAPS scores in the olanzapine plus SSRI group compared with those treated with an SSRI alone. Not surprisingly, there was also a significant increase in weight gain (13.2 lb [6 kg]) in the olanzapine group (Stein *et al.* 2002), and the concerns described earlier in regard to hyperlipidemia and cardiovascular disease risk for quetiapine are similar, if not even greater, for olanzapine

Aripiprazole

Aripiprazole, with a unique pharmacological profile of partial agonism at the dopamine$_2$ and serotonin$_{1A}$ receptors, has demonstrated efficacy in schizophrenia, bipolar disorder, and MDD. There have been few placebo-controlled studies evaluating aripiprazole in the treatment of PTSD, and most of the current evidence is based on retrospective chart reviews. Richardson *et al.* (2011) found that of 27 military veterans with PTSD and comorbid MDD that did not respond to initial SSRI treatment and who were later prescribed aripiprazole as augmentation, 10 individuals experienced a 20% or more reduction in PTSD Checklist for DSM-IV (PCL-4) scores, with greater reductions in reexperiencing and avoidance. Mello *et al.* (2008) evaluated aripiprazole monotherapy in 32 patients with PTSD in a 16-week open-label trial with a mean aripiprazole dosage of 9.6 mg/day. The average observed reduction in CAPS scores in the aripiprazole group was 38% (from 82.7 to 51.4). At the study end, 12 of the original 32 participants had only mild PTSD symptoms (CAPS score < 39), and 6 patients achieved remission (CAPS score < 20). Side effects of aripiprazole (e.g., anxiety, psychomotor agitation, or insomnia) led six individuals to drop out of the study before 16 weeks (Mello *et al.* 2008).

Other Antipsychotics

We are unaware of any PTSD studies with data on several of the newer atypical antipsychotic drugs, including lurasidone, lumateperone, asenapine, clozapine, iloperidone, and paliperidone. We are also unaware of any clinical trials with first-generation antipsychotic agents.

Anticonvulsants

Early environmental and interpersonal stressors have been implicated in altering future sensitivity to stress and vulnerability to PTSD. This "kindling-like" phenomenon, in addition to disturbances in GABA regulation posited in PTSD, has led researchers to explore anticonvulsant medications as a potential treatment option for individuals with PTSD (Keck *et al.* 1992; Kraus 2000). Frequency of anticonvulsant use among military veterans with PTSD has been increasing over the past decade; however, this trend may reflect increased treatment of comorbid disorders associated with PTSD (Shiner *et al.* 2017).

Topiramate

There have been several controlled studies evaluating topiramate in the treatment of PTSD (Lindley *et al.* 2007; Tucker *et al.* 2007; Yeh *et al.* 2011). Two placebo-controlled studies evaluated topiramate monotherapy for civilians with PTSD (Tucker *et al.* 2007; Yeh *et al.* 2011). The mean dosages of topiramate in these studies were 76 and

103 mg/day, respectively. After 12 weeks, investigators from both studies found no significant difference in total CAPS score reduction between groups. Lindley *et al.* (2007) evaluated adjunctive topiramate versus adjunctive placebo for individuals with combat-related PTSD who were continued on a stable antidepressant regimen. The investigators similarly found no difference in CAPS score reduction between groups. The most common side effects were insomnia, somnolence, and headache (Lindley *et al.* 2007).

Divalproex/Valproate

Divalproex has been examined in civilian and veteran populations as a monotherapy and adjunctive treatment for PTSD. However, no large placebo-controlled studies have demonstrated significant PTSD symptom reduction with treatment. Davis *et al.* (Davis *et al.* (2008) conducted a placebo-controlled trial of divalproex monotherapy in 82 individuals with PTSD, with a mean divalproex dosage of 2,309 mg/day and a mean serum level of 82 mg/L. The investigators found no difference in PTSD symptom reduction between the treatment and placebo groups after 8 weeks (Davis *et al.* 2008). Another randomized placebo-controlled study of 29 individuals with PTSD of divalproex titrated to target serum levels between 50 mg/mL and 125 mg/mL found no difference in symptom reduction after 10 weeks (Hamner *et al.* 2009). Routine use of divalproex for patients without other psychiatric comorbidities such as bipolar disorder is not recommended.

Other mood stabilizers and anticonvulsants have been investigated for the treatment of PTSD. Hertzberg *et al.* (1999) conducted a small placebo-controlled study of 15 individuals with PTSD using lamotrigine monotherapy up to 500 mg/day. Symptoms were assessed by clinician ratings at each visit using the SIP and the physician-administered Duke Global Rating for PTSD scale. Several case reports reviewing the effect of lithium in individuals with PTSD reported reductions in suicidal ideation and irritability; however, improvements in overall PTSD symptoms or symptom clusters were not found (Forster *et al.* 1995; Gupta and Knapp 2013). Studies examining adjunctive pregabalin and tiagabine monotherapy have not demonstrated significant therapeutic benefit for individuals with PTSD (Baniasadi *et al.* 2014; Davidson *et al.* 2007). Baniasadi *et al.* (2014) studied 37 veteran psychiatric inpatients in Iran with chronic PTSD who had been receiving SSRIs (citalopram 20-40 mg/day or sertraline 50-200 mg/day) and sodium valproate (1,000-1,800 mg/day) for a minimum duration of 1 month. Pregabalin (75 mg/day in week 1, 75 mg bid in week 2, and titrated to 150 mg bid for the remaining weeks 3-6) was added to the this medication regimen for the active-treatment group (n = 18) compared with a placebo-added control group (n = 19). PCL-4-Military scores were significantly reduced in both groups, and pregabalin was significantly more effective compared with placebo (P = 0.045), although not robustly so. No significant between-group differences in Ham-D and Ham-A scores were found (Baniasadi *et al.* 2014). Longer-term studies are needed to assess whether adjunctive pregabalin may be effective for PTSD. Gabapentin has demonstrated limited effectiveness as an adjunctive treatment for PTSD; however, no studies have shown gabapentin monotherapy to be effective. A retrospective study of 30 patients with PTSD treated with adjunctive gabapentin (300-3,600 mg/day) showed moderate improvements in nightmare frequency and sleep duration (Hamner *et al.* 2001). Two placebo-controlled studies evaluated gabapentin monotherapy in addition to an

active comparator, propranolol or pregabalin, as a preventive treatment for the development of PTSD and depressive symptoms following a traumatic event. Both studies reported no difference in symptom development between treatment groups and the placebo group (Fowler *et al.* 2012; Stein *et al.* 2007).

Anticonvulsants should not be used as a first-line treatment for individuals with PTSD and should only be considered for individuals with comorbid bipolar disorder who are unable to tolerate SSRI and/or SNRI medications or atypical antipsychotics.

Benzodiazepines

Benzodiazepines are effective anxiolytics for several anxiety disorders. Guina *et al.* (2015) performed a systematic review and meta-analysis of benzodiazepines for PTSD including four RCTs. Despite a few studies showing short-term improvement in sleep and anxiety, the overall evidence was in agreement with several PTSD treatment guidelines in concluding that benzodiazepines at best are ineffective for core PTSD symptoms and at worst may increase the risk of developing PTSD or may worsen PTSD symptoms (Guina *et al.* 2015). A large retrospective study of more than 200,000 veterans with PTSD treated in the VA system reported that those treated with benzodiazepines had higher rates of health care utilization, including emergency room visits, hospitalizations, and outpatient care, in addition to higher rates of suicidality and suicide attempts than those not prescribed benzodiazepines (Deka *et al.* 2018).

Risks of benzodiazepines in this population include the potential to develop dependency, withdrawal, and tolerance, especially in light of the frequency of comorbid substance use disorders in patients with PTSD. In first-line trauma-focused psychotherapies, benzodiazepines interfere with a patient's ability to feel and process their emotions and collude with the tendency to avoid; therefore, they are relatively contraindicated during psychotherapy for PTSD (Resick *et al.* 2017). Long-and short-term risks such as irritability or paradoxical activation, cognitive impairment, and risk of falls in elderly individuals, combined with a lack of efficacy and their potential to worsen symptoms, support the conclusion that the risks of benzodiazepines typically outweigh short-term benefits in the treatment of PTSD.

Prazosin

Prazosin is an antihypertensive and a_1-adrenergic receptor antagonist that crosses the blood-brain barrier and counteracts the potentially increased noradrenergic outflow that may contribute to nightmares in rapid eye movement sleep (Raskind 2020). Studies examining prazosin for PTSD have shown conflicting results. Raskind *et al.* (2016) used standing systolic blood pressure as an indicator of activity regulated by a_{1A}-adrenergic receptors on peripheral arteries to predict the effect of prazosin in active-duty soldiers after combat. For each 10-mmHg increase in baseline standing systolic blood pressure, there was a resultant 14-point decrease in the CAPS total score only for those who received prazosin (Raskind *et al.* 2016). In a more recent well-powered multicenter RCT, Raskind *et al.* (2018) demonstrated no significant difference between prazosin and placebo in 304 VA patients. Hypotheses for the negative results in this second trial included the following (Ressler 2018): First, patients with less severe PTSD were enrolled (psychosocial instability was an exclusion criterion). Second, sleep apnea was not an exclusion criterion and may have masked prazosin's effects. Third, those taking trazodone (a partial a_1-adrenergic antagonist) with benefit did not enroll (trazodone use was an exclusion criterion). Finally, other large VA trials have shown negative effects when the trial drug is already being used by many patients (i.e., successful responders might not have been eligible for the study) (Ressler 2018). In a systematic review and meta-analysis of six RCTs including the aforementioned Raskind *et al.* (2018) trial, a pooled analysis of 429 patients showed that prazosin produced significantly greater improvement in nightmares, sleep quality, and overall PTSD scores compared with placebo (Reist *et al.* 2021). In another meta-analysis of eight RCTs with prazosin that also included the Raskind *et al.* (2018) trial, treatment with prazosin produced significantly greater improvement in nightmares, but not in overall PTSD symptoms or sleep quality, compared with placebo (Zhang *et al.* 2020).

Imagery rehearsal therapy has shown large effect sizes in reducing nightmare frequency and distress (van Schagen *et al.* 2015). A meta-analysis of RCTs using imagery rehearsal therapy versus prazosin reported that prazosin effect sizes were larger but not significantly so (Yucel *et al.* 2020). Performing well in comparison with another evidence-based treatment for nightmares lends credence to the fact that for many, prazosin is effective in reducing trauma nightmares. It can be inferred that at the very least, a subset of patients with prominent a_1-adrenergic-mediated hyperarousal may benefit more from prazosin (Raskind 2020; Ressler 2018). An advantage is its general tolerability; the side effects of prazosin that differed significantly from placebo were dry mouth (Zhang *et al.* 2020), dizziness, lightheadedness, and urinary incontinence (Raskind *et al.* 2018). Symptomatic hypotension was rare but should be a consideration, especially for individuals with a history of hypotension or other cardiac issues at baseline and those at risk for falls.

Psychedelic Drug-Assisted Psychotherapy

Psychedelic drug-assisted psychotherapy is designed to utilize psychedelics as adjuncts to psychotherapy to enhance patients' ability to emotionally and cognitively process trauma via pharmacological reduction of fear and arousal, increase in trust, and assistance with memory consolidation (Krediet *et al.* 2020).

3,4-Methylenedioxymethamphetamine

MDMA promotes the release of serotonin, dopamine, and norepinephrine (Clemens *et al.* 2007) and is categorized as an entactogen because it increases comfort with expression of feelings (Bahji *et al.* 2020). MDMA increases oxytocin release, which is linked to the prosocial effects of MDMA (Dumont *et al.* 2009) and is postulated to improve the therapeutic alliance in psychotherapy (Mithoefer *et al.* 2016). Proposed mechanisms for the effects of MDMA-assisted psychotherapy in PTSD improvement include reduced cerebral blood flow to the amygdala, increased connectivity between the hippocampus and amygdala, facilitation of synaptic plasticity via cholinergic signaling, and activation of brain-derived neurotrophic factor (BDNF) signaling that induces changes in memory (Feduccia and Mithoefer 2018). MDMA may enhance memory reconsolidation and processing in addition to fear extinction (Feduccia and Mithoefer 2018).

In terms of its safety profile, changes in postreceptor signaling suggest that chronic MDMA use may lead to chronic reductions in serotonin signaling (Benningfield and Cowan 2013; Parrott 2014). Chronic users may also experience hyponatremia, memory deficits, persistent sleep abnormalities, depression, and increased aggression, and pregnant women who misuse MDMA have been reported to have children with lower-quality motor scores (Parrott 2014). Much of the safety data just described are derived from retrospective reports with unclear confounders, such as polydrug use disorders (Mithoefer *et al.* 2016). Side effects of acute MDMA intoxication include difficulty concentrating, confusion, blurred vision, sweating, and intensification of negative emotional states (Parrott 2014). If mood is enhanced while taking MDMA and this results in a post-MDMA depressive effect (even if transient), there are questions of inducing drug-seeking behavior to "feel good" (Parrott 2014). Others argue that MDMA is safe if taken a limited number of times, in safe dosages, and with supervised administration and that brief use is not a fair comparison to chronic use of the drug (Feduccia *et al.* 2019; Morgan 2020). Side effects that occurred at a frequency at least twice that in the control group in Phase II trials with MDMA-assisted therapy included diarrhea, difficulty concentrating, dizziness, heavy legs, impaired gait or balance, jaw clenching or tight jaw, nausea, lack of appetite, paresthesia, perspiration, sensitivity to cold, thirst, nystagmus, and weakness (Feduccia *et al.* 2019).

In MDMA-assisted therapy, MDMA is not the treatment per se but rather a means to enhance participation in the primary treatment modality, psychotherapy (Morgan 2020). In Phase II trials, participants received the following: three preparatory psychotherapy sessions; two to three blinded 8-hour psychotherapy sessions with MDMA (75-125 mg) or a comparator or placebo (0-40 mg MDMA); and three 90-minute nondrug psychotherapy visits following each MDMA-assisted session (Feduccia *et al.* 2019). In a systematic review and meta-analysis of five Phase II trials conducted between 2004 and 2013 in the United States, Spain, and Switzerland with 106 participants, MDMA-assisted therapy demonstrated a large effect size in treatment-refractory PTSD, with improvements in remission rates and a significant reduction in PTSD symptoms, and with gains maintained from 2 to 74 months (Bahji *et al.* 2020). Data pooled over all six Phase II trials showed statistical significance over the control, with a between-group Cohen's *d* (effect size) of 0.9, compared with effect sizes for prior Phase II trials of 0.45-0.56 for paroxetine and 0.31-0.37 for sertraline. Feduccia *et al.* (2019) concluded that MDMA-assisted psychotherapy was superior to paroxetine and sertraline in terms of having greater safety and efficacy and lower dropout rates, leading the FDA to grant MDMA-assisted psychotherapy a breakthrough therapy designation in 2017.

A randomized double-blind, placebo-controlled Phase III study was conducted at 11 U.S., 2 Canadian, and 2 Israeli sites, with a total of 42 and 37 participants in the MDMA and placebo groups, respectively, who completed treatment. Manualized therapy with MDMA or with placebo consisted of three preparatory and nine integrative therapy sessions. The MDMA dose ranged from 80 to 180 mg (compared with 75-125 mg in Phase II trials). The experimental sessions consisted of an initial dose and an optional supplemental half-dose 1.5 to 2.5 hours after the initial dose; session 1 included 80 + 40 mg, and sessions 2 and 3 included 120 + 60 mg. Six participants declined the supplemental dose or chose not to escalate the dose. A history of substance use disorder, severe childhood trauma, or dissociative PTSD subtype did not affect treatment outcomes. MDMA produced significantly greater reductions in CAPS-5 scores compared with placebo ($P < 0.0001$, $d = 0.91$) and significantly greater decreases in Sheehan Disability Scale scores ($P < 0.0116$, $d = 0.43$). For treatment completers, the mean (+- SD) change in CAPS-5 scores was [?]24.4 +- 11.6 in the MDMA group and [?]13.9 +- 11.5 in the placebo group. Two months after the last session, 67% of the MDMA group no longer met criteria for PTSD, compared with 32% of the control group. Reported adverse effects from MDMA included muscle tightness, decreased appetite, nausea, hyperhidrosis, feeling cold, and a transient increase in blood pressure and heart rate. MDMA did not induce adverse events of suicidality, abuse potential, or QT prolongation; however, longer-term follow-up is necessary to fully exclude these and other potential side effects (Mitchell *et al.* 2021).

A remaining source of contention is that most of the MDMA research has been conducted by one group of researchers, the Multidisciplinary Association for Psychedelic Studies (Morgan 2020). Some feel that the evidence is insufficient to recommend MDMA-assisted psychotherapy over more conventional treatments (Bahji *et al.* 2020; Reiff *et al.* 2020); however, the initial Phase III results are promising.

Psilocybin

Psilocybin (phosphoryloxy-*N*,*N*-dimethyltryptamine), derived from mushrooms or in synthetic form, is metabolized to psilocin, which is a serotonin transporter inhibitor and a serotonin$_{2A}$ receptor partial agonist that also binds to serotonin$_{2C}$, serotonin$_{1A}$, and serotonin$_{1B}$ receptors (Rickli *et al.* 2016). Psilocybin received an FDA breakthrough therapy designation for use in depression (Krediet *et al.* 2020) but not for PTSD. For the treatment of depression, a postulated mechanism of action is through the default mode network and frontal brain connectivity changes; psilocybin may cause system-level alterations that improve mood (Johnson *et al.* 2019). Psilocybin has been shown to enhance fear extinction in mice (Catlow *et al.*

2013) and reduce amygdala reactivity in humans (Kraehenmann *et al.* 2015), both of which could prove beneficial in PTSD treatment. Data from animal studies can be interpreted to show that psilocybin may create episodes of behavioral flexibility that enhance learning of new psychotherapeutic skills. Hypothetically, altered sensory perception and integration of details may also allow for reduced rigidity or ruminative thinking (De Gregorio *et al.* 2021). In terms of suicidal ideation (often present in PTSD), data show that psilocybin increases mystical or spiritual experiences (Griffiths *et al.* 2018), which could confer protection from suicide from a religious or spiritual perspective (Nobile *et al.* 2020).

Psilocybin-assisted psychotherapy involves at least one predrug psychotherapy session, nondirected drug-assisted sessions that include multiple check-ins, and at least one postdrug session (Carhart-Harris *et al.* 2016; Griffiths *et al.* 2016; Kaelen *et al.* 2018). In the dose range of 10-25 mg (Krediet *et al.* 2020), effects have been shown to last 3-6 hours (Passie *et al.* 2002). Side effects include mild elevations in blood pressure and heart rate, transient vomiting or nausea, stressful emotional experiences (e.g., confusion and anxiety), and alterations in perception (e.g., visual or auditory

hallucinations); psilocybin is not deemed to cause serious side effects or dependence in small, supervised doses (Johnson *et al.* 2018). Although current RCTs are lacking, past unstructured research with smaller samples demonstrated positive effects in survivors of trauma (Krediet *et al.* 2020), and current studies are under way.

Cannabis

D-9-Tetrahydrocannabinol (THC) is one of the major psychoactive ingredients in marijuana (Hindocha *et al.* 2020), and cannabidiol (CBD) is a nonpsychotomimetic component (Pisanti *et al.* 2017). The endogenous endocannabinoid system is composed of cannabinoid receptors CB_1 and CB_2. CB_1 receptors are expressed in the amygdala, hippocampus, and prefrontal cortex; CB_2 receptors are located primarily in the periphery but have been shown to be present in the aforementioned brain areas as well (Orsolini *et al.* 2019). CBD imparts lower CB_1 and CB_2 receptor affinity than THC (Pisanti *et al.* 2017). The endogenous endocannabinoid system also includes endogenous cannabinoids such as *N*-arachidonoyl ethanolamine (anandamide) and 2-arachidonoylglycerol (Hindocha *et al.* 2020). An anandamide-degrading enzyme, fatty acid amide hydrolase (FAAH), has been hypothesized to be a target for novel PTSD medications. In an RCT of healthy male participants, JNJ-42165279, a novel drug that inhibits FAAH, was administered for 4 days (Paulus *et al.* 2021). The results showed that the drug reduced activation in the amygdala, anterior cingulate, and insula during a face recognition task; it also increased activation in the anterior cingulate, bilateral anterior insula, and right inferior frontal cortex during anticipation of an aversive interoceptive event but did not affect fear conditioning or extinction (Paulus *et al.* 2021).

A recent systematic review examined several types of cannabinoids for PTSD treatment (Orsolini *et al.* 2019). Results for medical cannabis use were conflicting, with some showing a reduction in PTSD symptoms (Bonn-Miller *et al.* 2014; Greer *et al.* 2014) and others showing worsening PTSD symptomatology, violent behavior, and substance use (Wilkinson *et al.* 2015). In an open-label pilot study of 10 patients who received orally absorbable THC (5 mg bid) as an adjunct to other medications, there was a statistically significant reduction in PTSD severity, a decrease in nightmare frequency, and improvement in sleep quality (Roitman *et al.* 2014).

A small retrospective chart review case series of 11 patients demonstrated that oral CBD reduced scores on the PTSD Checklist for DSM-5 (PCL-5) by 28% (from 51 to 37) after 8 weeks of treatment with no side effects. Study limitations included confounders such as allowing for other concurrent PTSD treatments (e.g., therapy, medication), inconsistent dosing of CBD, and failure to exclude patients who were using cannabis on their own (Elms *et al.* 2019).

Nabilone, a synthetic THC analog and CB_1 receptor agonist that is FDA approved for treatment of chemotherapy-induced nausea and vomiting, was examined in a placebo-controlled double-blind crossover study in Canadian military members with PTSD. This drug reduced CAPS scores for recurring and distressing dreams (Jetly *et al.* 2015). In a retrospective chart review study with 104 participants with PTSD in a correctional facility, those given nabilone showed a decrease in PCL-4 scores and nightmares. Confounders included that most participants had severe mental illness, many had cannabis use disorder, and only patient-rated outcomes were used (Cameron *et al.* 2014; Hindocha *et al.* 2020). In an open-label clinical trial of 47 patients with PTSD, nabilone reduced nightmares in 72% of participants (Fraser 2009).

A 2020 systematic review of cannabinoids for PTSD covering studies up to December 2018 found only one RCT and nine other studies that showed promise for this treatment modality. Small sample sizes and low-quality ratings were limiting, and the investigators concluded that there was insufficient evidence to support cannabinoid use for routine treatment of PTSD (Hindocha *et al.* 2020).

Common side effects of cannabis use in the abovementioned studies included dry mouth, headaches, feeling "stoned," sedation, lightheadedness or dizziness, and stomach irritation (Cameron *et al.* 2014; Elms *et al.* 2019; Fraser 2009; Roitman *et al.* 2014). A more significant but less common side effect is psychosis, which is more frequent in those with a genetic predisposition (Cameron *et al.* 2014).

The potential for a substance use disorder is a valid concern, especially in regard to long-term cannabis use. A longitudinal observational study of 361 veterans deployed after September 11, 2001, found no evidence of decreased intrusive symptoms or PTSD remission in long-term cannabis users and concluded that long-term use may be associated with a worsening of intrusive symptoms (Metrik *et al.* 2020). In a nationwide longitudinal VA study of veterans with opioid use disorder and PTSD, cannabis use was not associated with a substantial reduction in opioid use, days of substance use, abstinence, or severity of PTSD symptoms (De Aquino *et al.* 2020). The potential for a cannabis use disorder remains an unanswered question; however, results from an earlier study showed that individuals with PTSD were more likely to use cannabis as a coping mechanism, with the perception, whether valid or not, that it could help reduce their PTSD symptoms (Cougle *et al.* 2011).

Ketamine

Ketamine is an *N*-methyl-D-aspartate (NMDA) receptor antagonist. Its mechanism of action in terms of antidepressant effects and impact on PTSD is not yet fully elucidated (Stein and Simon 2021). Impaired synaptic connectivity may detrimentally affect neuroplasticity in PTSD and is postulated to be connected to glutamate dysregulation via processes including reduced signaling via BDNF. In rats, ketamine given after stress normalized hippocampal decreased BDNF concentrations (Zhang *et al.* 2015). Ketamine may theoretically improve PTSD symptoms by stimulating glutamate release and increasing BDNF release and activation of the Akt/molecular target of rapamycin pathway, ultimately resulting in the creation of new dendritic spines (Krystal *et al.* 2017). In a rodent study, extinction exposure and ketamine increased levels of molecular target of rapamycin complex 1 (mTORC1) and c-Fos (a marker of neuronal activity) in the medial prefrontal cortex, supporting the above hypothesis in terms of enhancing fear extinction (Girgenti *et al.* 2017). Alternatively, ketamine may block extrasynaptic NMDA glutamate receptors to increase BDNF (Krystal *et al.* 2017). There is now substantial evidence from both preclinical and clinical investigations demonstrating that ketamine acts in part on endogenous opioid systems. Seminal studies by Williams *et al.* (2018) conclusively showed that the m opioid receptor antagonist naltrexone completely abolishes the antidepressant and antisuicide effects of ketamine. Several laboratory animal studies support these findings. Ketamine may act as a m opioid agonist like other opioid analgesics and/or may increase the release of endogenous opioids such as b-endorphin.

Ketamine is a dissociative anesthetic that is also a drug of abuse. The recent FDA approval of intranasal use of esketamine for treatment-resistant depression sparked investigation of its use in comorbid depression and PTSD and in PTSD alone. Several single case reports showed efficacy in reducing PTSD symptom severity; however, symptoms returned 2 weeks after ketamine treatment (D'Andrea and Sewell 2013; Donoghue *et al.* 2015; Womble 2013).

Earlier studies were discordant, with some evidence that ketamine may worsen PTSD. A retrospective study of motor vehicle accident survivors who received a peritraumatic dose of racemic ketamine, esketamine, or opioids en route to the hospital found that esketamine strongly increased acute symptoms of dissociation, reexperiencing, and avoidance, whereas racemic ketamine mildly increased them. The esketamine group also showed significantly more severe PTSD symptoms compared with the other two groups 1 year after trauma (Schonenberg *et al.* 2005). Combat veterans with PTSD (*n* = 147) who received ketamine perioperatively for burn injuries had a lower prevalence of PTSD than those who did not receive ketamine (McGhee *et al.* 2008). In a follow-up study with a larger sample (*n* = 289), the two groups did not show any difference in syndromal PTSD rates (McGhee *et al.* 2014). Subsequent studies have been more positive. Oral ketamine was shown to reduce hospital stay duration by 70% in a study of 37 patients with comorbid depression and PTSD (Hartberg *et al.* 2018). In an RCT (*n* = 41), single-dose intravenous ketamine was superior to the active control (midazolam) in reducing PTSD and depressive symptoms in an initial study with 2-week follow-up (Feder *et al.* 2014). In a subsequent RCT (*n* = 30), six intravenous infusions of either ketamine or the active control (midazolam) were given over 2 consecutive weeks. Based on improvement in scores on the CAPS-5 and MADRS, 20% of the control group responded to treatment (liberally defined as > 30% symptom improvement after 2 weeks of initial infusion), specifically in the clusters of avoidance, intrusions, and negative alterations in mood and cognitions, compared with 67% of the ketamine group. For responders, 27.5 days was the median time to loss of treatment response (Feder *et al.* 2021). This result was consistent with findings in an earlier open-label repeated ketamine infusion study of six infusions over a 12-day period. Investigators demonstrated a PTSD remission rate of 80% and a treatment-resistant depression response rate of 93%, with symptom relapse on days 41 and 20 after treatment for PTSD and depression, respectively (Albott *et al.* 2018).

In terms of ketamine's side-effect and safety profile, one participant in the study by Feder *et al.* (2014) dropped out because of a lack of improvement and possible worsening of PTSD symptoms after two ketamine infusions, and another had hypertension that required treatment. Other minor side effects included transient dissociative symptoms, blurred vision, dizziness, nausea, vomiting, headache, and fatigue. Patients with a psychotic or substance use disorder were excluded; therefore, ketamine's potential for abuse or exacerbation of psychosis was not examined (Feder *et al.* 2021). A systematic review of ketamine use for depression reported a similar side-effect profile, and the authors noted that more research is needed to assess long-term effects, especially when given in repeated dosing, as repeated use of ketamine in anesthesia or chronic pain, and/or recreationally has been associated with hepatotoxicity, urotoxicity, and deficits in cognition, including short-and long-term memory (Short *et al.* 2018). Questions remain regarding long-term safety, effectiveness, tolerability, and whether combining ketamine with evidence-based psychotherapy may help sustain a treatment response.

Nitrous Oxide

Nitrous oxide, an inhaled anesthetic, is a noncompetitive NMDA receptor antagonist that mechanistically may work in a manner similar to ketamine for PTSD. In a case

report series of three veterans with PTSD, nitrous oxide was delivered via face mask in a single 1-hour treatment of anesthetic inhalation of 50% nitrous oxide and 50% oxygen. CAPS-5 scores were obtained at baseline and 1 week after drug administration, with response defined as a reduction of 12 points at day 7. Two of the three patients met this response criterion, with a reduction of 16 and 17 points in CAPS-5 scores at day 7. On the Impact of Events Scale-Revised version, the two responders showed almost complete resolution of symptoms on day 1: one had sustained symptom improvement, and the other had a gradual return to baseline by day 7. Side effects included nausea, poor concentration, and vomiting (Varias *et al.* 2020).

Nitrous oxide completely suppressed stress-enhanced fear learning in a rodent study (Rau *et al.* 2009), suggesting that it may be useful in preventing PTSD. Nitrous oxide was used to prevent memory consolidation in 52 healthy participants exposed to violent film clips who were given either 50% nitrous oxide or oxygen for 30 minutes (Das *et al.* 2016).

Negative intrusions were not statistically different between groups; however, the nitrous oxide group showed a markedly faster reduction in intrusion frequency over 7 days. Similar between-group measurements of heart rate variability and sleep point against these variables influencing the results. The nitrous oxide group experienced more dissociation, which warrants concern for possible exacerbation of PTSD (Das *et al.* 2016). This study of laboratory-induced "trauma" suggests that nitrous oxide may speed the reduction of intrusions after trauma, but these findings must be replicated in larger PTSD samples.

D-Cycloserine

D-Cycloserine is a partial NMDA agonist and has been shown to improve fear extinction in animals (Hoskins *et al.* 2021). Of two studies assessing D-cycloserine as an add-on therapy for PTSD, one demonstrated no difference from placebo (Heresco-Levy *et al.* 2002) and one showed a significant decrease only in symptom intensity in the first of two 4-week intervention periods (Attari *et al.* 2014). In a recent meta-analysis examining D-cycloserine as an add-on to psychotherapy, the following four studies used different doses and time points for administration and reported conflicting results (Hoskins *et al.* 2021). Among women who had experienced sexual abuse, D-cycloserine did not differ from placebo when administered 1 hour before face-to-face prolonged exposure sessions (de Kleine *et al.* 2012). In a small group of survivors of the World Trade Center attack on September 11, 2001, remission rates were higher for D-cycloserine plus cognitive-behavioral therapy (CBT) via virtual reality exposure (VRE) than for placebo plus CBT via VRE (Difede *et al.* 2014). In a small study of combat veterans, the placebo plus exposure group had greater symptom reduction than the D-cycloserine plus exposure group, and three of the D-cycloserine-treated participants experienced worsening of their PTSD symptoms (Litz *et al.* 2012). A randomized trial of veterans comparing D-cycloserine plus VRE, alprazolam plus VRE, or placebo plus VRE showed no significant differences among the three groups in the primary outcome measures (i.e., CAPS and PTSD symptom scale scores). However, salivary cortisol and startle responses were significantly lower in the D-cycloserine group, suggesting that reduced reactivity in this group may have been related to enhanced extinction learning that was associated with the D-cycloserine group only (Rothbaum *et al.* 2014). In addition, a pediatric study reported that D-cycloserine plus manualized youth CBT exposure therapy was not significantly different from placebo plus the same exposure therapy (Scheeringa and Weems 2014). Side effects in these studies were minor, did not differ significantly from placebo, and included nausea, headache, drowsiness, irritability (in pediatric patients), dizziness, and dry mouth (Baker *et al.* 2018). Currently, evidence is lacking to recommend D-cycloserine for the treatment of PTSD.

Neuromodulation

Electroconvulsive Therapy

Modern electroconvulsive therapy (ECT), which utilizes brief and ultrabrief pulses of rectangular rather than sine wave current, has substantially reduced the severity of cognitive side effects in comparison with older versions of this therapy while maintaining significant effectiveness for various mental disorders such as depression. ECT has also been shown to increase hippocampal neurogenesis and cortical volume (Ousdal *et al.* 2020). The effects of ECT on memory consolidation may be of potential benefit for individuals with PTSD, as previous research has shown the potential sensitivity of reactivated emotional memories to disruption following ECT treatments in individuals with depression (Kroes *et al.* 2014).

Multiple retrospective analyses have examined the impact of ECT in patients with comorbid MDD and PTSD (Ahmadi *et al.* 2016; Kaster *et al.* 2018; Watts 2007) and have demonstrated reductions in depressive and PTSD symptoms. In the largest retrospective case-control study examining the efficacy of ECT in treating PTSD and depression comorbidity (3,485 participants with comorbid MDD and PTSD [of whom 92 were treated with ECT and 3,393 were not treated with ECT] and 18,679 without MDD or

PTSD), ECT was associated with a reduction in depressive and PTSD symptoms; PTSD symptoms improved independent of depressive symptoms (Ahmadi *et al.* 2016). This study also reported that individuals with PTSD who received ECT treatment exhibited reductions in suicidality as well as cardiovascular and all-cause mortality (Ahmadi *et al.* 2016). Margoob *et al.* (2010) conducted the only identified open-label prospective clinical trial to date for adults with PTSD symptoms that failed to respond to at least four different antidepressants along with 12 sessions of CBT. Of the 20 individuals who began the fixed course of six bilateral ECT treatments, all but 3 completed the study. At the study end, the mean CAPS score had decreased from 91.7 to 55.1 and depressive symptoms assessed using the MADRS had decreased from 23.5 to 10.1 (Margoob *et al.* 2010). The evidence supporting ECT treatment for individuals with PTSD is still limited; however, for appropriate patients with comorbid depressive symptoms or severe and refractory PTSD symptoms, ECT should be considered as an effective alternative treatment option.

Repetitive Transcranial Magnetic Stimulation

rTMS is FDA approved for major depressive disorder and has been increasingly investigated for the treatment of PTSD. In rTMS, a magnetic field is created that safely passes through the scalp and skull and alters the excitability and activity of cortical and, to a lesser extent, subcortical structures--often the dorsolateral prefrontal cortex (dlPFC) or medial prefrontal cortex. Although studies have investigated left-sided and bilateral treatments (Boggio *et al.* 2010; Carpenter *et al.* 2018; Philip *et al.* 2016, 2018), the majority of supporting evidence indicates the likelihood that right-sided treatment is superior (Kan *et al.* 2020). Low-and high-frequency (1 and 15-20 Hz) stimulation has opposing effects on neural excitability and blood flow. Low-frequency stimulation decreases excitability, whereas high-frequency stimulation increases it. However, both forms of stimulation have demonstrated effectiveness in treating core symptoms of PTSD, indicating that improvement may be independent of stimulation intensity (Kozel *et al.* 2019).

Evidence supports the effectiveness of rTMS as monotherapy and as an adjunctive treatment for PTSD. Cohen *et al.* (2004) conducted a study in 24 patients randomly assigned to 2 weeks of 10 daily treatments (10 Hz, 1 Hz, or sham) over the left dlPFC. The authors found that individuals receiving excitatory stimulation had significant reductions in PTSD and anxiety symptoms measured via the CAPS and Ham-A, respectively (Cohen *et al.* 2004). Another sham-controlled crossover study of nine individuals evaluated a combination of exposure therapy and 1-Hz rTMS over the right dlPFC, and the investigators observed significant improvements in hyperarousal symptoms measured via CAPS scores (Osuch *et al.* 2009).

Intermittent theta-burst stimulation (iTBS) is a patterned form of rTMS that has also demonstrated effectiveness in the treatment of PTSD. iTBS utilizes short bursts of high-frequency (50-Hz) stimulation repeated at 5-Hz intervals that deliver stimulation pulses more quickly, allowing a reduction in overall treatment time (5 vs. 30 minutes) compared with traditional rTMS. In a recent study, Philip *et al.* (2019) randomly assigned 50 veterans with PTSD to 10 days of sham-controlled iTBS followed by 10 unblinded treatments. At 2 weeks, active iTBS treatment was associated with significant improvement in Social and Occupational Functioning Assessment Scale scores (Philip *et al.* 2019).

Transcranial Direct Current Stimulation

In transcranial direct current stimulation (tDCS), a small current (usually 2 mA) is run through the brain via electrodes, leading to subthreshold shifts in neuronal resting membrane potential, with anodal orientation increasing cortical excitability and cathodal orientation decreasing it (Priori *et al.* 2009). Previous investigations have demonstrated moderate effectiveness for tDCS in treating depression (Bennabi and Haffen 2018; Brunoni *et al.* 2013), although this modality is not FDA approved. Ahmadizadeh *et al.* (2019) conducted a tDCS sham-controlled trial for individuals with PTSD (n = 44) and found improvements in hyperarousal and cognitive symptoms as well as in depressive symptoms after 10 sessions of bilateral tDCS over the dlPFC. Another sham-controlled investigation incorporating tDCS as an adjunctive treatment to VRE therapy reported significantly greater reductions in hyperarousal symptoms in the treatment group compared with the control group (van't Wout-Frank *et al.* 2019). Although the generalizability of these findings is limited by small sample sizes, these studies offer a framework for the feasibility and potential therapeutic benefit of tDCS treatments in the future.

Stellate Ganglion Block

A stellate ganglion block (SGB) involves an injection of a local anesthetic, typically under ultrasound or fluoroscopic guidance, between C6 and C7 into the stellate ganglion nerve bundle. SGB inhibits sympathetic nerve impulses and has been used to successfully treat disorders such as complex regional pain syndrome, hot flashes, migraines, facial pain, and upper-extremity pain (Peterson *et al.* 2017). When SGB was used to treat these conditions, some improvements in psychological symptoms were observed, leading researchers to test its effectiveness in PTSD. This temporary sympathetic block may help reduce fight-or-flight responses, which are tied to hyperarousal in PTSD. It is postulated that when severe, hyperarousal symptoms may reduce the efficacy of treatment (McCurry *et al.* 2020; Stein *et al.* 2012). Brain areas associated with hyperarousal in PTSD, including the hypothalamus, amygdala, and insular cortex, are all accessible via the stellate ganglion afferents (Westerhaus and Loewy 2001).

A case series of 166 patients receiving SGBs showed that 70% had clinically significant improvement (a reduction of at least 10 points in PCL-4-Military scores), which persisted for 3-6 months (Mulvaney *et al.* 2014). In anecdotal clinical case reports of SGBs administered to 24 patients after a year of psychotherapy and medication management, 75% showed meaningful improvement in PTSD scores (Lipov and Ritchie 2015). The initial RCT for SGB for PTSD showed that the range of improvement in PTSD symptoms was not statistically different from saline placebo (Hanling *et al.* 2016). There were many methodological limitations, including 1) using a lesser-known anesthetic and dose, 2) not injecting in the same location on each participant, 3) not utilizing accepted outcome measures for PTSD, and 4) using a secondary gain variable because many participants were in the midst of compensation evaluations for PTSD (Peterson *et al.* 2017). In a second, larger RCT involving 113 active-duty service members recruited from U.S. Army pain management clinics, patients who had stable symptoms with psychotropic medications and a PTSD Checklist-Civilian Version for DSM-IV (PCL-C-4) score greater than 32 received either a right-sided SGB or a sham saline injection at weeks 0 and 2 and were followed for 8 weeks (Olmsted *et al.* 2020). To reduce the secondary gain component, patients undergoing compensation evaluations were excluded from the study. CAPS-5 total symptom severity scores showed a statistically significant adjusted mean change of -12.6 points for SGB and of -6.1 points for sham injection. These results were promising but less generalizable, as the participants had stable disease with their medication regimen, traumatic brain injury was an exclusion criterion, and PTSD symptoms were mild to moderate (Olmsted *et al.* 2020; Raskind 2020).

Advantages of using an SGB include the possibility that it may be perceived by patients as less stigmatizing than medication or psychotherapy because it is a physical procedure (Summers and Nevin 2017) and that, if effective, it is fast acting, working minutes to days after the procedure (Peterson *et al.* 2017). Verification that an SGB was successful can be made within 15 minutes of injection via symptoms including ptosis, miosis, anhidrosis, and enophthalmos, all part of temporary Horner's syndrome (Lipov and Ritchie 2015; Mulvaney *et al.* 2014; Peterson *et al.* 2017). A considerable disadvantage is the need for an anesthesiologist and continuous monitoring in case of accidental intravascular injection (Peterson *et al.* 2017). Other possible adverse effects include severe complications such as bleeding, seizures, pneumothorax, and spinal cord trauma (Lipov and Ritchie 2015). There are methodological issues around a 1992 German questionnaire survey of approximately 39 anesthesiology departments with 45,000 SGBs performed, which reported a rate of severe complications (e.g., convulsions and pneumothorax) of 1.7 per 1,000 (Peterson *et al.* 2017; Wulf and Maier 1992). A 2015 publication on SGB and PTSD showed no adverse outcomes from 250 SGBs conducted under fluoroscopy and suggested that ultrasonographic guidance would further enhance safety (McLean 2015).

The precise mechanism of action of SGB in the treatment of PTSD is unknown. Studies have been limited to 3 months of follow-up (Peterson *et al.* 2017). Longer-term effects have been hypothesized to last as a result of SGB leading to a reduction in nerve growth factor, mediating decreased sympathetic nerve sprouting and norepinephrine availability (Lipov and Ritchie 2015). More studies are needed to assess outcomes and long-term effects in more generalizable populations. SGBs show promise as an adjunct that may reduce some PTSD symptoms that would otherwise serve as barriers to care or successful symptom reduction and remission.

Conclusion and Future Directions

Since the advent of PTSD as an official clinical disorder in DSM-III (American Psychiatric Association 1980), researchers have striven to identify effective pharmacological treatments. Despite the often profound symptom burden and destructive life consequences that result from the disorder, the FDA has approved only two medications for PTSD over the past 40 years. Many categories of standard psychotropic medications, including antipsychotics, mood stabilizers, and antidepressants, are being used, but many patients' symptoms do not respond and too few reach remission. Neuromodulation, particularly with PTSD and comorbid depression, and psychedelic-assisted psychotherapies show promise but do not yet have robust enough evidence for their use over standard care. Evidence-based psychotherapies, such as cognitive-processing therapy and prolonged exposure, are considered first-line treatments for PTSD and have been more effective, with a greater number of completers with remitted PTSD; however, nonresponders remain. Focus on the brain regions involved in treatment response and the mechanism of action in several systems, including the hypothalamic-pituitary-adrenal axis, synaptic plasticity, and neurogenesis, has spawned new targets for research. Examples are summarized below:

- Although the glucocorticoid receptor antagonist mifepristone (RU486) has not been reported to have a significant direct effect in humans as a PTSD treatment to date (DePierro *et al.* 2019), it has been found to improve verbal learning, which may impact the treatment course (Golier *et al.* 2016).
- GSK561679, a corticotropin-releasing factor receptor type 1 (CRF1) antagonist, did not separate from placebo overall but did produce significant symptom reduction in a subset of women who had experienced childhood abuse and were hypothesized to have CRF1 receptor hyperactivity (Dunlop *et al.* 2017).
- Brexanolone, an intravenous formulation of the endogenous neurosteroid allopregnanolone, has been approved for postpartum depression and is being studied for PTSD.
- Studies targeting the neuropeptide Y system (DePierro *et al.* 2019) and factors leading to and promoting resilience spark hope for new treatment approaches to PTSD.

Unlike many psychiatric disorders, PTSD is associated with a stressor event, thereby opening the door for timely research focused not only on treatment but also on prevention of the disorder itself. Agents to assist with extinction recall and memory encoding are being explored, such as the b-adrenergic antagonist propranolol and dopamine precursor L-dopa, which was recently shown to aid in boosting reactivation of amygdala extinction encodings but not in improving extinction recall in women with PTSD (Cisler *et al.* 2020). In addition, a Cochrane Review concluded that there was evidence for hydrocortisone in the role of PTSD prevention (Amos *et al.* 2014). Epigenetic changes and the search for biomarkers to help develop and predict treatment response are beyond the scope of this chapter, but they hold promise for the field in moving to a more personalized medicine approach. What has been clear over the years is that there is not a "one-size-fits-all" treatment for PTSD. Further investigation into different potential subtypes of PTSD may help elucidate differential responses to current and novel treatments.

CHAPTER 52

Treatment of Obsessive-Compulsive Disorder

Reilly R. Kayser, M.D.
H. Blair Simpson, M.D., Ph.D.

With the publication of DSM-5 (American Psychiatric Association 2013), OCD is no longer considered an anxiety disorder and instead has moved to its own disorder class--Obsessive-Compulsive and Related Disorders. There have been a number of advances in the pharmacological treatment of OCD over the past decade, including new strategies for monotherapy and augmenting with or combining medications. In addition, researchers have begun to explore the use of nutraceuticals, pharmacological enhancement of psychotherapy, and neuromodulation/neurosurgical treatment approaches. In this chapter, we review findings on each of these topics, highlighting key results from randomized controlled trials and select open-label trials of relevance to the treatment of OCD.

OCD is a debilitating psychiatric condition characterized by recurrent intrusive thoughts (obsessions) and repetitive behaviors or mental acts (compulsions) that lead to distress and functional impairment (Stein *et al.* 2019). Once believed to be quite rare, OCD is now recognized to be more common than schizophrenia and a substantial contributor to the global burden of disease (Baxter *et al.* 2014). In the National Comorbidity Survey and subsequent National Comorbidity Survey Replication, the lifetime prevalence rate for OCD was approximately 2.3%, whereas the 12-month prevalence was 1.2% (Kessler *et al.* 2012; Ruscio *et al.* 2010).

A robust evidence base supports both psychotherapeutic and psychopharmacological approaches to treating OCD, the latter of which are the focus of this chapter. Neuromodulation treatments are also reviewed. Pharmacological treatment will relieve symptoms for a majority of patients (Skapinakis *et al.* 2016) and, when combined optimally with cognitive-behavioral therapy (CBT), can help as many as 69% to achieve wellness (i.e., minimal symptoms [Simpson *et al.* 2021]).

This chapter aims to provide practitioners with a focused overview of the state of the art in evidence-based pharmacological treatments for OCD. We review first-and second-line pharmacological treatments for OCD (e.g., serotonin reuptake inhibitors [SRIs], including selective serotonin reuptake inhibitors [SSRIs] and clomipramine), other agents used as monotherapy when these agents are not effective (e.g., serotonin-norepinephrine reuptake inhibitors [SNRIs]), medications used to augment SRIs (e.g., neuroleptics, glutamate modulators, and stimulants), and medications that show promise and are currently being examined (e.g., ketamine). In addition, we discuss recent developments in neuromodulation/neurosurgical approaches to treating OCD, and we highlight differences in the approach to pharmacological treatment of children and adolescents with OCD compared with adults.

The majority of the studies referenced in this chapter use the Yale-Brown Obsessive Compulsive Scale (Y-BOCS) to define treatment response. Considered the gold-standard measure of OCD symptoms, the Y-BOCS is a 10-item clinician-rated assessment of obsession and compulsion severity over the past week (Goodman *et al.* 1989b). The scale ranges from 0 to 40, with a score of 16 or greater indicating clinically significant OCD that warrants treatment. The studies in children and adolescents discussed herein use the Children's Yale-Brown Obsessive Compulsive Scale (CY-BOCS [Scahill *et al.* 1997]), a similar clinician-rated measure adapted for use in pediatric populations. Using the Y-BOCS alone or coupled with other measures such as the Clinical Global Impression Scale (Guy 1976), measures of response and remission have been developed and used in clinical trials. Although the importance of standardizing these outcomes has been discussed (Simpson *et al.* 2006) and global guidelines have been proposed (Mataix-Cols *et al.* 2020), some variations persist, making comparisons across studies more difficult. These variations are noted when necessary in the following review.

Monotherapy for Obsessive-Compulsive Disorder

Table 52-1 summarizes the medications used as monotherapy for OCD.

TABLE 52-1. Monotherapies for obsessive-compulsive disorder

Class	Role in treatment	Clinical considerations	Supporting research
SSRIs	First line (adults), second line after CBT (children and adolescents)	Dosages above the FDA-recommended maximum are occasionally required	Geller *et al.* 2001
		Adverse effects include gastrointestinal upset and sexual dysfunction; risk increases at higher dosages	Goodman *et al.* 1989a
		Minimum trial duration of 8-12 weeks	Hollander *et al.* 2003a Liebowitz *et al.* 2002 March *et al.* 1998 Rasmussen *et al.* 1997 Riddle *et al.* 2001 Tollefson *et al.* 1994
Clomipramine	Second line (adults), third line (children and adolescents), particularly in patients whose symptoms have not	Some evidence suggests slight benefit over SSRIs, although this finding has been inconsistent	DeVeaugh-Geiss *et al.* 1992

Note. 5-HT = 5-hydroxytryptamine (serotonin); CBT = cognitive-behavioral therapy; MAOIs = monoamine oxidase inhibitors; N/A = not available; SNRIs = serotonin-norepinephrine reuptake inhibitors; SSRIs = selective serotonin reuptake inhibitors.

Class	Role in treatment	Clinical considerations	Supporting research
	responded to two or more SSRI trials		
		Greater adverse-effect burden than SSRIs; may cause anticholinergic (e.g., dry mouth, constipation), antihistaminergic (e.g., weight gain, sedation), and anti- a-adrenergic (e.g., hypotension) effects	Karameh and Khani 2015
		Need to monitor plasma levels, maintaining clomipramine-desmethylclomipramine at < 500 ng/mL	Koran *et al.* 2006
		Intravenous use not recommended outside of the most refractory cases	Leonard *et al.* 1991
			March *et al.* 1990
			Stein *et al.* 1992
			Zohar and Judge 1996
SNRIs (venlafaxine, duloxetine)	Can be tried when SSRIs fail but are not FDA approved	Only venlafaxine studied in controlled trials	Dell'osso *et al.* 2008
		Evidence for duloxetine limited to case reports	Denys *et al.* 2004b
		No controlled studies of desvenlafaxine or levomilnacipran	Dougherty *et al.* 2015
			Mowla *et al.* 2016
			Ravizza *et al.* 2001
Mirtazapine	Can be tried in those with symptoms resistant to SSRIs, clomipramine, and SNRIs but is not FDA approved	Antagonist at a_2-adrenergic receptors with a secondary effect of blockade at 5-HT_{2A}, 5-HT_{2C}, and 5-HT_3 receptors	Koran *et al.* 2005b
			Pallanti *et al.* 2004

Note. 5-HT = 5-hydroxytryptamine (serotonin); CBT = cognitive-behavioral therapy; MAOIs = monoamine oxidase inhibitors; N/A = not available; SNRIs = serotonin-norepinephrine reuptake inhibitors; SSRIs = selective serotonin reuptake inhibitors.

Class	**Role in treatment**	**Clinical considerations**	**Supporting research**
Other serotonergic agents (MAOIs, vilazodone, vortioxetine)	To be established	Mechanism suggests theoretical potential for efficacy, but untested to date	N/A

Note. 5-HT = 5-hydroxytryptamine (serotonin); CBT = cognitive-behavioral therapy; MAOIs = monoamine oxidase inhibitors; N/A = not available; SNRIs = serotonin-norepinephrine reuptake inhibitors; SSRIs = selective serotonin reuptake inhibitors.

Selective Serotonin Reuptake Inhibitors

The first-line medications for both adults and children with OCD are SSRIs. Of these, fluvoxamine, fluoxetine, and sertraline have been FDA approved for treating OCD in both children and adults. Paroxetine is also FDA approved for treating adult but not pediatric patients with OCD, whereas escitalopram and citalopram are not FDA approved for either group although these medications are often used off-label (Koran *et al.* 2007). As their name implies, SSRIs inhibit the reuptake of serotonin into presynaptic nerve terminals, thereby increasing synaptic serotonin concentrations. This in turn increases inhibition by presynaptic serotonin autoreceptors, which initially decreases but ultimately increases the firing rate of serotonergic neurons as autoreceptors become desensitized with continued exposure (Nutt *et al.* 1999) (for further details, see Chapter 12, "Fluoxetine and Fluvoxamine," and Chapter 13, "Sertraline and Paroxetine").

The efficacy of SSRIs in the treatment of OCD was first established in 1989, when investigators conducted a randomized double-blind, placebo-controlled study in 42 adults with OCD and found that 6-8 weeks of treatment with fluvoxamine ([?] 300 mg/day) led to greater reductions in Y-BOCS scores than placebo (Goodman *et al.* 1989a). Since then, the efficacy of SSRIs in adults with OCD has been confirmed by more than 20 studies in over 3,200 patients (Issari *et al.* 2016; Soomro *et al.* 2008). These include randomized double-blind, placebo-controlled trials of fluoxetine (Tollefson *et al.* 1994), sertraline (Rasmussen *et al.* 1997), and paroxetine (Hollander *et al.* 2003a), in addition to fluvoxamine. Since the initial studies were conducted, meta-analyses continue to support the safety, tolerability, and efficacy of SSRIs for adults with OCD (Issari *et al.* 2016; Skapinakis *et al.* 2016).

Although there have been relatively fewer studies of SSRIs in children and adolescents, large randomized placebo-controlled trials similarly support the safety and superiority of fluvoxamine (Riddle *et al.* 2001), fluoxetine (Geller *et al.* 2001; Liebowitz *et al.* 2002), and sertraline (March *et al.* 1998) to placebo. Subsequent meta-analyses also support moderate to large effect sizes for these agents (Sanchez-Meca *et al.* 2014). However, unlike in adults, meta-analyses of SSRIs in children and adolescents have found that these agents are associated with smaller effect sizes and higher side-effect burden compared with CBT (Sanchez-Meca *et al.* 2014; Watson and Rees 2008). For this reason, most guidelines recommend CBT as a first-line treatment for children and adolescents with mild to moderate OCD (Geller and March 2012), with SSRIs to be used as a second-line approach for patients with severe symptoms or whose symptoms do not respond to an initial trial of CBT.

Few head-to-head comparisons of the six SSRIs listed earlier have been conducted. However, the current data do not support any meaningful differences in efficacy between them, although their adverse effects may vary (Pittenger *et al.* 2021).

Dosage

Compared with dosages used for anxiety or depressive disorders, higher dosages of SSRIs are associated with greater efficacy for treating OCD (Bloch *et al.* 2010; Ninan *et al.* 2006). American Psychiatric Association practice guidelines recommend occasional use of dosages as high as fluvoxamine 450 mg/day, fluoxetine 120 mg/day, sertraline 400 mg/day, paroxetine 100 mg/day, and escitalopram 60 mg/day (Koran *et al.* 2007). However, higher SSRI dosages are also associated with higher rates of treatment dropout as a result of adverse effects such as initial gastrointestinal upset or sexual dysfunction (Stein *et al.* 2019). Thus, optimal dosing requires a careful balance between efficacy and minimization of side effects.

Citalopram has been linked to QTc prolongation on electrocardiogram (ECG) monitoring at higher dosages, leading the FDA to recommend avoiding dosages above 40 mg/day (or 20 mg/day for adults age [?] 60 years) because of the associated risk for cardiac arrhythmia (U.S. Food and Drug Administration 2012). Although subsequent analyses have not revealed a clear association between citalopram and adverse cardiac effects (Hutton *et al.* 2017), treatment with high-dosage citalopram (and perhaps its therapeutically active enantiomer escitalopram) should nonetheless be pursued with caution; ECG monitoring is also advisable for elderly patients and individuals with a history of cardiac events (Kayser 2020).

Treatment Duration

Patients with OCD may also require a longer duration of SSRI treatment than those with anxiety or depressive disorders. American Psychiatric Association guidelines recommend a treatment duration of 8-12 weeks to determine efficacy (Koran *et al.* 2007). Two meta-analyses reported that initial improvement may occur as early as 2 weeks after starting an SSRI, and the greatest incremental improvements tended to accrue earlier in treatment (Issari *et al.* 2016; Varigonda *et al.* 2016). Moreover, in an open-label trial of fluoxetine in treatment-naive patients, those whose symptoms improved the most during the first 4 weeks were most likely to develop a full clinical response (i.e., [?] 35% decrease in Y-BOCS scores) by week 12 (da Conceicao Costa *et al.* 2013). These data suggest that early response may help predict the long-term benefit of a particular SSRI for patients with OCD, although some with limited early improvement will still achieve a response to a trial of 12 weeks or longer (Rasmussen *et al.* 1997).

For patients who achieve a clinically meaningful response, treatment for an additional 12-24 months is generally recommended (Baldwin *et al.* 2014; Greist *et al.* 2003). To our knowledge, there are no published data regarding the clinical outcome of lowering the SSRI dosage during this maintenance phase of treatment. However, a meta-analysis reported that symptoms recurred for approximately 36% of patients who discontinued SSRIs (Batelaan *et al.* 2017). Extended treatment may therefore be necessary to prevent relapse in some cases.

Side Effects

Common side effects of SSRIs include gastrointestinal upset (e.g., nausea, diarrhea), headache, dry mouth, drowsiness, insomnia, nervousness or restlessness, and sexual dysfunction (Chang *et al.* 2022). These effects occur most frequently during the first 2 weeks after initiation, although approximately half of patients report experiencing at least one side effect during maintenance treatment (Hu *et al.* 2004). Less commonly, weight gain may occur during SSRI treatment. Rare and severe side effects of SSRIs include increased risk for bleeding, syndrome of inappropriate antidiuretic hormone secretion, and serotonin syndrome (Chang *et al.* 2022).

Studies suggesting that SSRIs may increase the risk for suicidal thoughts and behaviors in children, adolescents, and young adults led the FDA to issue a black box warning regarding their use in these populations (U.S. Food and Drug Administration 2004). Thus, careful assessment of the risks and benefits of SSRIs is critical before starting treatment in young people, as is close monitoring for clinical worsening and the emergence of suicidality once treatment has begun.

Discontinuation and Relapse Management

The decision to discontinue medications should be made with the patient's informed consent following discussion of the known risks (e.g., relapse, withdrawal symptoms) and benefits (e.g., resolution of SSRI-induced sexual dysfunction). Switching to a longer-acting SSRI (e.g., fluoxetine) and tapering medications gradually over the course of weeks to months (vs. days to weeks) may reduce the risk for withdrawal and/or relapse (Horowitz and Taylor 2019). Although few studies have evaluated the efficacy of different relapse prevention strategies, experts generally recommend developing a relapse management plan in collaboration with the patient and their family, which may include starting CBT or reinitiating medication (Fineberg *et al.* 2020).

Treatment Resistance

Unfortunately, only a minority of patients with OCD will achieve minimal symptoms (defined as a Y-BOCS score [?] 12) after an initial SRI trial (Farris *et al.* 2013). When this happens, evidence-based pharmacological strategies include optimizing the dosage and duration of treatment, switching to another medication, or augmenting with an additional medication (Pittenger *et al.* 2021). Of note, there is also strong evidence to support combining medication with CBT for OCD at this stage, with one trial showing larger effect sizes for augmenting SSRIs with CBT versus augmenting with risperidone (Simpson *et al.* 2013). Although a detailed discussion of CBT for OCD is beyond the scope of this chapter, CBT is a first-line treatment for OCD alongside SSRIs and should always be considered in cases of SSRI treatment resistance.

When SSRI treatment is ineffective despite a trial of adequate dosage and duration, switching to a different agent is a reasonable next step. Although switching to another SSRI may help some patients, the likelihood of success decreases with each additional trial (Pittenger 2021). Switching to clomipramine is more likely to be beneficial when the response to a first or second SSRI is limited (Koran *et al.* 2007).

Clomipramine

Clomipramine is a tricyclic antidepressant and potent, nonselective SRI (Murphy *et al.* 1989). By inhibiting norepinephrine, acetylcholine, and histamine reuptake, clomipramine and other tricyclic antidepressants also increase activity at the receptors for these neurotransmitters. Clomipramine was first identified as a potential OCD treatment in the 1960s (Fernandez Cordoba and Lopez-Ibor Alino 1967). Subsequently, a pair of landmark studies in a total of 520 patients (study 1, n = 239 adults with OCD symptoms for at least 2 years; and study 2, n = 281 adults with OCD symptoms for at least 1 year) found that 10 weeks of clomipramine treatment was generally well tolerated, was significantly more effective than placebo, and led to 38% and 41% reductions in Y-BOCS scores, respectively (Clomipramine Collaborative Study Group 1991). These studies established clomipramine's efficacy and ultimately led to its becoming the first FDA-approved treatment for OCD in the United States. Meta-analyses suggest that clomipramine is slightly more efficacious than SSRIs (Hirschtritt *et al.* 2017). However, the initial clomipramine trials included fewer patients with treatment-resistant OCD compared with more recent SSRI studies (Stein *et al.* 2019), and a series of direct comparisons between SSRIs and clomipramine found their efficacies to be equivalent (Bisserbe *et al.* 1997; Lopez-Ibor *et al.* 1996; Zohar and Judge 1996).

Compared with SSRIs, clomipramine's side-effect profile is less favorable. Clomipramine's activity at nonserotonergic receptor targets gives it the potential to cause anticholinergic effects (e.g., dry mouth, constipation), antihistaminergic effects (e.g., sedation, weight gain), and anti-a-adrenergic effects (e.g., hypotension). Clomipramine has also been linked to a reduced seizure threshold and to greater risk for cardiac arrhythmias; as a result of the latter, ECG results should be monitored periodically during clomipramine treatment (Koran *et al.* 2007). To prevent clomipramine toxicity, treatment guidelines recommend avoiding clomipramine dosages above the FDA maximum of 250 mg/day in most cases (Koran *et al.* 2007). Although not correlated with treatment efficacy (Pittenger 2021), plasma levels of clomipramine and its metabolite desmethylclomipramine can help with toxicity monitoring and should be

kept at a combined level of less than 500 ng/mL (Koran *et al.* 2007). Given that SSRIs are similarly effective, are more tolerable, and require less intensive safety monitoring, clomipramine should generally be reserved for use after SSRIs.

Clomipramine treatment has also been evaluated in children and adolescents with OCD, including two trials that supported its FDA approval for patients older than age 10 years. The first was a 10-week randomized double-blind, placebo-controlled trial of clomipramine versus placebo in 16 children and adolescents with OCD (March *et al.* 1990). The investigators found a trend toward substantial benefit from clomipramine over placebo that did not reach statistical significance; however, post hoc analyses revealed significant improvement in CY-BOCS scores among patients with neurological symptoms (March *et al.* 1990). In the second trial, an 8-week randomized double-blind, placebo-controlled trial in 60 children and adolescents with OCD at five individual sites, DeVeaugh-Geiss *et al.* (1992) found a mean reduction in CY-BOCS scores of 37% in the clomipramine group compared with 8% in the placebo group. Although meta-analyses indicate that effect sizes for clomipramine are comparable to or larger than those for SSRIs in the treatment of children and adolescents with OCD (Varigonda *et al.* 2016; Watson and Rees 2008), this agent has various adverse effects, and its use with pediatric populations is generally reserved for cases in which multiple trials of CBT and SSRIs have failed (Geller and March 2012).

Although the abovementioned studies all used oral clomipramine, intravenous clomipramine has also been tested in a few small trials in adults with OCD. By preventing first-pass metabolism, this formulation theoretically could mitigate side effects (Fallon *et al.* 1992) while also quickly generating therapeutic dosages to hasten symptom relief (Koran *et al.* 1997). Whereas some small trials reported intravenous clomipramine to be more effective in patients whose symptoms responded poorly to oral formulations (Fallon *et al.* 1992, 1998; Karameh and Khani 2015; Koran *et al.* 1997), results from other studies were mixed (Koran *et al.* 2006; Mundo *et al.* 1999). Because its efficacy remains equivocal and its availability is limited, intravenous clomipramine is rarely used.

Other Serotonergic Agents

Only SSRIs and clomipramine have been definitively shown to be beneficial as standalone pharmacotherapies for OCD. However, other agents have demonstrated some promise and may be considered when patients' symptoms do not respond to SSRIs and/or clomipramine. Although these agents act by a variety of mechanisms, each interacts with the serotonin system to an extent. In all trials reviewed next, treatment response was defined as a Y-BOCS score reduction of at least 35% unless otherwise specified.

Serotonin-Norepinephrine Reuptake Inhibitors

Given the established efficacy of SRIs, other serotonergic agents such as SNRIs could also theoretically improve OCD symptoms. However, there have only been a few small SNRI trials in patients with OCD to date, with mixed results.

Venlafaxine. Of the SNRIs, venlafaxine is the most studied in patients with OCD. In a 12-week randomized double-blind comparison trial in 150 adults with OCD, investigators found equivalent rates of clinical response and adverse effects for venlafaxine ([?] 300 mg/day) and paroxetine ([?] 60 mg/day) (Denys *et al.* 2003). A second trial in 47 patients used a similar enrollment strategy and design to compare the effects of venlafaxine ([?] 350 mg/day) and clomipramine ([?] 225 mg/day) (Albert *et al.* 2002). Similar efficacy was shown for both agents, but individuals treated with venlafaxine experienced fewer adverse effects (Albert *et al.* 2002). In addition, two studies evaluated the effects of switching to either another SSRI or venlafaxine for adults with OCD that responded poorly to an initial SSRI trial. One trial reported greater response among participants switched to venlafaxine (Ravizza *et al.* 2001), whereas the other found higher response rates (defined in this study as a Y-BOCS score reduction of at least 25%) for those who received an alternative SSRI (Denys *et al.* 2004b). An observational study from an Indian specialty clinic reported that approximately 45% of adults with symptomatic OCD despite SSRI treatment achieved response when switched to venlafaxine (Balachander *et al.* 2019).

Duloxetine. Several case reports and at least one case series describe adult patients with OCD whose symptoms improved after switching from an SSRI to duloxetine (Dell'osso *et al.* 2008). A small open-label trial in 20 medication-free adults with OCD reported that around half responded to 17 weeks of treatment with duloxetine ([?] 120 mg/day), but 35% did not complete the protocol (Dougherty *et al.* 2015). Finally, Mowla *et al.* (2016) conducted a controlled trial of 46 patients with OCD symptoms that did not respond to initial SSRI treatment. Patients were switched to 12 weeks of treatment with duloxetine versus a second SSRI, and response rates (defined as a Y-BOCS score reduction [?] 25%) and mean reductions in Y-BOCS scores were similar for both groups (total Y-BOCS score decrease of 10.5 vs. 10.6, respectively [Mowla *et al.* 2016]).

Other serotonin-norepinephrine reuptake inhibitors. Controlled studies of the other two FDA-approved SNRIs, desvenlafaxine and levomilnacipran, have not been conducted in patients with OCD.

Mirtazapine

Mirtazapine is an atypical antidepressant that acts primarily as an antagonist at a_2-adrenergic receptors. It also has secondary effects on serotonergic signaling, including blockade of the serotonin 5-HT_{2A}, 5-HT_{2C}, and 5-HT_3 receptors. One open-label trial found moderate symptomatic improvement among 30 adults with OCD who received mirtazapine monotherapy, titrated to 60 mg/day, over 12 weeks (Koran *et al.* 2005b). In another study, 49 adults with OCD were randomly assigned to 12 weeks of treatment with citalopram (20-80 mg/day) either alone or combined with mirtazapine (15-30 mg/day). Mirtazapine seemed to accelerate the initial response to citalopram, although it did not improve overall efficacy (Pallanti *et al.* 2004). With so few data, the benefit of mirtazapine to patients with OCD remains equivocal.

Monoamine Oxidase Inhibitors

Monoamine oxidase inhibitors (MAOIs) act by inhibiting monoamine oxidase activity, thus preventing the breakdown of monoamine neurotransmitters (e.g., serotonin, norepinephrine, and dopamine) and increasing their availability (Hendriksen and Groenink 2015). Despite these agents' efficacy in the treatment of depression and anxiety disorders, trials of MAOIs in OCD are currently scarce; the existing trials had small sample sizes and yielded mixed results. One double-blind, randomized crossover trial in 13 adults with OCD found significant symptomatic improvement following treatment with clomipramine but not the MAOI clorgyline (which is not currently available in the United States [Insel *et al.* 1983b]). A second double-blind trial comparing 12 weeks of treatment with either clomipramine or phenelzine in 30 adults with OCD reported that both agents significantly improved symptoms but did not differ from each other (Vallejo *et al.* 1992). Finally, a third double-blind study compared phenelzine to fluoxetine and placebo in 54 adults with OCD and found that both agents, although significantly better than placebo, led to only mild improvement (< 3 points on the Y-BOCS [Jenike *et al.* 1997]).

A recent case series described nine adults whose OCD had failed to respond to phenelzine treatment in at least two prior medication trials (Grant *et al.* 2021a). Three patients experienced marked response, three experienced moderate, and three experienced no response to phenelzine treatment. Patients whose symptoms improved the least did not have a comorbid anxiety disorder (Grant *et al.* 2021a). Although these results suggest that MAOIs may have some value for treating patients with OCD with comorbid anxiety disorders, the current data are insufficient to support their use outside of patients whose symptoms are unresponsive to multiple medication trials.

Novel Serotonergic Drugs

Over the past decade, two novel serotonergic drugs (vilazodone and vortioxetine) were FDA approved for the treatment of depression. In addition to inhibiting serotonin reuptake, these agents have unique mechanistic profiles compared with other approved drugs: vilazodone is a 5-HT$_{1A}$ receptor partial agonist and a moderate inhibitor of both norepinephrine and dopamine reuptake, whereas vortioxetine is a 5-HT$_{1A}$ full agonist, 5-HT$_{3}$ antagonist, and modulator of several other serotonin receptor subtypes (Faquih *et al.* 2019). Although their novel activities suggest that these agents could be useful for treating OCD, only two case reports describe positive effects from vortioxetine treatment in patients with the disorder (De Berardis *et al.* 2017; Naguy *et al.* 2019), and there are no published data regarding vilazodone.

Serotonin Reuptake Inhibitor Augmentation and Combination Strategies

In the event of a partial response to SRI monotherapy, the next step is typically to combine an SRI with another agent. Of the combinatorial strategies, adding an antipsychotic has the greatest evidence base from randomized controlled trials. There is also some evidence to support adding a glutamate modulator, combining an SSRI with clomipramine, or adding a stimulant.

Table 52-2 summarizes the medications used in augmentation/combination treatment approaches for OCD.

TABLE 52-2. Pharmacological combination and augmentation of serotonin reuptake inhibitors

Medication class/ role in treatment	Clinical considerations	Supporting research
Antipsychotics		
Augmentation of SRIs in adults	Meta-analyses show the greatest support for risperidone ([?] 2-3 mg/day); studies also support aripiprazole ([?] 10-15 mg/day).	Ercan *et al.* 2015
	Haloperidol may have some additional benefit for patients with comorbid tics but may be difficult to tolerate because of extrapyramidal symptoms (e.g., tremor, muscle rigidity) and other side effects.	Grillault Laroche and Gaillard 2016
	There is limited evidence to support using paliperidone, olanzapine, or quetiapine.	Hollander *et al.* 2003b
	Unlike with SRIs, there is no evidence of additional benefit from high-dosage antipsychotics.	McDougle *et al.* 1994, 2000
	Clozapine may induce OCD symptoms, possibly due to 5-HT$_{2A/2C}$ receptor antagonism.	Muscatello *et al.* 2011
	Not recommended for children and adolescents, given limited data and risk for weight gain or metabolic syndrome and other side effects.	Pessina *et al.* 2009
		Ravizza *et al.* 1996
		Sayyah *et al.* 2012b
	Simpson *et al.* 2013	
Glutamate modulators		

Note. 5-HT = 5-hydroxytryptamine (serotonin); NAC = *N*-acetylcysteine; SRI = serotonin reuptake inhibitor; SSRI = selective serotonin reuptake inhibitor.

Medication class/ role in treatment	Clinical considerations	Supporting research
Augmentation of SRIs in adults	NAC is recommended as an initial agent given its favorable safety profile, availability over the counter in the United States, and reasonable evidence of benefit. Meta-analyses found that NAC ([?] 3,000 mg/day) had moderate benefits when added to SRI treatment in adults and children with OCD.	Afshar *et al.* 2012
	Askari *et al.* 2022	
	Riluzole, troriluzole, topiramate, lamotrigine, gabapentin, pregabalin, glycine, sarcosine, and amantadine have all been studied in small trials but cannot be recommended based on current data.	Gadallah *et al.* 2020
	Memantine ([?] 20 mg/day) had modest benefits in controlled trials in adults. As a result of its greater risk for adverse effects (e.g., fatigue) and concerns regarding the homogeneity of the supporting studies, it is recommended as a second-line agent in patients whose symptoms are unresponsive to NAC.	Ghaleiha *et al.* 2013 Hezel *et al.* 2009 Kishi *et al.* 2018 Lafleur *et al.* 2006 Paydary *et al.* 2016 Rodriguez *et al.* 2016a
Sarris *et al.* 2015		
Combination SSRIs and clomipramine		
Only SSRI-resistant cases in adults	Typically involves adding low-dosage clomipramine (< 75 mg/day) to an SSRI, with the goal of enhancing serotonergic tone while minimizing the risk for clomipramine adverse effects.	Diniz *et al.* 2010, 2011
	Small controlled trials of this approach had mixed results.	Marazziti *et al.* 2008
	May increase risk for adverse effects (e.g., QTc prolongation, sexual side effects) due to pharmacodynamic and pharmacokinetic interactions.	
Not recommended outside of refractory cases in adult patients.		
Other augmentation agents		

Note. 5-HT = 5-hydroxytryptamine (serotonin); NAC = *N*-acetylcysteine; SRI = serotonin reuptake inhibitor; SSRI = selective serotonin reuptake inhibitor.

Medication class/ role in treatment	**Clinical considerations**	**Supporting research**
Only SSRI-resistant cases in adults	Other agents showing efficacy in small controlled trials include stimulants (amphetamine), pindolol, and the 5-HT_{3A} receptor antagonists ondansetron, granisetron, and tropisetron.	Askari *et al.* 2012 Kalyani *et al.* 2017 Koran *et al.* 2009 Sassano-Higgins and Pato 2015 Shalbafan *et al.* 2019
Sharafkhah *et al.* 2019		

Note. 5-HT = 5-hydroxytryptamine (serotonin); NAC = *N*-acetylcysteine; SRI = serotonin reuptake inhibitor; SSRI = selective serotonin reuptake inhibitor.

Antipsychotics

Multiple placebo-controlled studies suggest that antipsychotics (i.e., dopamine D_2 receptor antagonists) have modest benefits for adults with OCD that responds incompletely to SRIs, although only around one-third of patients will benefit (Bloch *et al.* 2006; Dold *et al.* 2015; Veale *et al.* 2014; Zhou *et al.* 2019). Improvement with antipsychotic augmentation tends to occur in the initial 2-4 weeks of treatment; thus, prolonged trials are generally not recommended (Fineberg *et al.* 2015). Although there have been no dosage-finding studies of antipsychotics in patients with OCD, low dosages are generally recommended because of these agents' association with weight gain, metabolic syndrome, and other adverse effects; furthermore, there is little evidence that higher dosages lead to additional improvement (Pittenger 2021). At any dosage, the risk/benefit ratio of antipsychotic augmentation should be continuously reevaluated throughout treatment (Matsunaga *et al.* 2009). Of note, there have been no controlled trials of antipsychotics in children and adolescents with OCD. Given their potential for long-term adverse effects in children and adolescents (e.g., weight gain, metabolic syndrome), antipsychotics should generally be avoided in this population.

Haloperidol

Haloperidol was one of the first augmentation agents to be studied in OCD and is the most widely researched of the first-generation antipsychotics (Pittenger 2021). Adults with OCD whose symptoms were unresponsive to SSRIs experienced symptomatic improvement with haloperidol augmentation in one open-label and two double-blind, placebo-controlled trials (Li *et al.* 2005; McDougle *et al.* 1990, 1994). These studies found higher response rates (defined as a Y-BOCS score reduction [?] 35%) among patients with a history of tics. However, support for a specific benefit to patients with OCD and comorbid tics was inconsistent in subsequent meta-analyses (Bloch *et al.* 2006; Veale *et al.* 2014; Zhou *et al.* 2019). Haloperidol was also poorly tolerated in these studies, owing to high rates of extrapyramidal symptoms (e.g., tremor, rigidity, or dyskinesias). Although clarification of these findings is needed, given the available data, it is reasonable to reserve haloperidol augmentation for patients with OCD with contraindications to second-generation antipsychotics (which are less likely to cause extrapyramidal symptoms) or those with comorbid tics.

Risperidone

Risperidone is the augmentation agent that has been most tested in controlled trials. Three small randomized placebo-controlled trials in adults with OCD that did not respond to prior SSRI treatment found that symptoms improved with risperidone augmentation (Erzegovesi *et al.* 2005; Hollander *et al.* 2003b; McDougle *et al.* 2000). The average risperidone dosage in these studies was between 2 and 3 mg/day. Subsequent meta-analyses suggested that risperidone augmentation may have greater efficacy compared with other antipsychotics (Dold *et al.* 2015; Veale *et al.* 2014; Zhou *et al.* 2019). However, a trial in adults with SRI-treated OCD who still had clinically significant symptoms reported no difference between those randomly assigned to 8 weeks of risperidone (n = 40) and those receiving placebo augmentation; patients randomly assigned to CBT augmentation (n = 40) had better outcomes than both the risperidone and placebo augmentation groups (Simpson *et al.* 2013). Instead of suggesting that risperidone augmentation is ineffective, these findings may reflect sampling differences between this study and the three prior risperidone trials. For example, all but two participants in the study by Simpson *et al.* (2013) achieved at least a partial response

to their SSRI, whereas participants in the previous trials had symptoms that were completely unresponsive to SSRIs. Moreover, participants recruited to a trial in which they could receive medication or CBT (as in Simpson *et al.* 2013) may have different treatment preferences than those who enroll in a medication trial (as in the previous studies), and these preferences can affect the outcome of treatment (Patel and Simpson 2010; Patel *et al.* 2017). Together, the results of these four studies support pursuing CBT as a first alternative when patients' symptoms do not respond to SRI treatment; for patients who do not obtain symptom improvement with or are uninterested in CBT, a trial of risperidone is a reasonable alternative.

Aripiprazole

Several studies have also examined aripiprazole augmentation in patients with OCD symptoms that were partially or completely unresponsive to ongoing SRI treatment. For example, two open-label trials in 9 and 20 adults with SSRI-unresponsive OCD (Dar *et al.* 2021; Pessina *et al.* 2009) found small but statistically significant improvements in Y-BOCS scores following augmentation. In addition, two placebo-controlled OCD trials--one in 30 adults whose symptoms were unresponsive to SSRIs or clomipramine (Muscatello *et al.* 2011) and another in 39 adults with SSRI-unresponsive symptoms (Sayyah *et al.* 2012b)--found greater improvement in Y-BOCS scores with aripiprazole augmentation compared with placebo. In a recent head-to-head comparison, aripiprazole also showed greater efficacy than quetiapine augmentation of SSRI treatment in 33 adults with OCD over 12 weeks of treatment (Talaei *et al.* 2020). In these studies, aripiprazole was generally well tolerated at dosages between 10 and 15 mg/day.

Although there have been no controlled trials of any antipsychotics in children and adolescents with OCD to date, a few case series and small open-label trials have examined the effects of aripiprazole in this population. Aripiprazole is potentially of greater interest in treating children and adolescents, given its lower likelihood of causing weight gain, metabolic syndrome, and other adverse effects compared with risperidone and other antipsychotics. Indeed, a review of this sparse literature suggests that aripiprazole is tolerable in children and adolescents with OCD and may have modest benefits when added to an SSRI (Thamby and Jaisoorya 2019). Nonetheless, these results must be confirmed in controlled trials before aripiprazole can be recommended for treating children and adolescents with OCD in clinical practice.

Quetiapine

Several studies have evaluated quetiapine's efficacy in augmenting SRI treatment of adults with OCD, with mixed results. For example, two placebo-controlled randomized trials in 27 and 40 adults with SRI-unresponsive OCD found decreased Y-BOCS scores after 8 weeks of quetiapine augmentation of SRI treatment (Atmaca *et al.* 2002; Denys *et al.* 2004a). However, three randomized placebo-controlled trials in 49, 21, and 40 adults with SRI-unresponsive OCD found that quetiapine did not improve Y-BOCS scores compared with placebo (Carey *et al.* 2005; Fineberg *et al.* 2006; Kordon *et al.* 2008). Head-to-head comparisons involving quetiapine augmentation have also been equivocal. In one trial in 44 female adult inpatients with OCD that responded poorly to SRI treatment, investigators found a greater response rate for quetiapine augmentation compared with aripiprazole; however, the mean reduction in Y-BOCS scores for both groups was small (< 3 points) and baseline symptoms were more severe in the aripiprazole group (Shoja Shafti and Kaviani 2015). In another trial, 40 adults with OCD and poor fluoxetine response received quetiapine, clomipramine, or placebo; both clomipramine and placebo led to greater improvement in Y-BOCS scores than quetiapine (Diniz *et al.* 2011). Based on these data, there is currently insufficient evidence to support quetiapine augmentation of OCD treatment in most situations.

Olanzapine

There have been several open-label studies of olanzapine augmentation of OCD treatment but only three controlled trials to date. A double-blind, placebo-controlled trial in 26 adults with an incomplete SSRI response reported that 46% achieved response to olanzapine (i.e., [?] 25% reduction in Y-BOCS scores), whereas none achieved response with placebo (Bystritsky *et al.* 2004). However, a similarly designed trial in 48 adults meeting similar criteria failed to replicate this finding (Shapira *et al.* 2004). More recently, a trial comparing olanzapine, aripiprazole, and L-methylfolate in 56 adults with OCD and an incomplete SSRI response found modestly greater reductions in symptoms with both olanzapine and aripiprazole treatment compared with L-methylfolate (which itself had little effect [Dar *et al.* 2021]). Weight gain is common with olanzapine and was reported by patients in all three of the abovementioned studies. Further evaluation of the efficacy of olanzapine augmentation in OCD is needed before its use can be recommended.

Paliperidone

One randomized controlled trial examined the effects of paliperidone versus placebo in 34 adults with OCD who experienced an incomplete response to SSRIs (Storch *et al.* 2013). Although OCD symptoms improved for patients who received paliperidone over 8 weeks, this effect did not differentiate from placebo. Until better-powered studies can be conducted, the efficacy of paliperidone augmentation in OCD is considered inconclusive.

Clozapine and Antipsychotic-Induced Obsessive-Compulsive Disorder Symptoms

Despite its efficacy for psychosis, clozapine is not thought to be effective in OCD; however, this has never been formally tested in a clinical trial (Pittenger *et al.* 2021). In fact, there is evidence that clozapine can induce OCD symptoms in some patients, which may relate to its antagonism of 5-HT$_{2A}$ and 5-HT$_{2C}$ receptors (Grillault Laroche and Gaillard 2016). There are case reports of other antipsychotics inducing OCD symptoms when delivered without an SSRI, although these associations have not been clearly established (Pittenger *et al.* 2021). Although a detailed discussion is beyond the scope of this chapter, strategies to manage clozapine-induced OCD symptoms in individuals with psychotic disorders may include dosage reduction and addition of aripiprazole (Kim *et al.* 2020).

Stimulants/Amphetamine

Although dopamine receptor antagonists (i.e., antipsychotics) are more commonly used, stimulant medications that increase dopaminergic signaling have also been studied as potential OCD treatments. Two small placebo-controlled crossover trials in

12 and 11 patients with OCD found that a single dose of D-amphetamine (30 mg) led to greater acute improvement in symptoms than placebo (Insel *et al.* 1983a; Joffe *et al.* 1991). The second of these trials also evaluated a single dose of methylphenidate (40 mg) but failed to find any difference in effect compared with placebo (Joffe *et al.* 1991), a finding shared by an earlier open-label trial of a single dose of methylphenidate in 11 patients with OCD (Joffe and Swinson 1987).

Subsequent trials focused on use of stimulants to augment SRI treatment. A small double-blind trial in 21 patients with refractory OCD found that both D-amphetamine (30 mg) and caffeine (which was used as an active comparator) improved symptoms when added to an SRI (Koran *et al.* 2009). However, interpreting these data is challenging, considering that one-third of the patients were taking SNRIs, which do not have established efficacy in OCD. More recently, a randomized double-blind trial in 44 adults with OCD unresponsive to SRIs found significantly greater improvement in symptoms over 8 weeks when methylphenidate (36 mg/day) was added to fluvoxamine (250 mg/day) compared with placebo (Zheng *et al.* 2019).

These preliminary data suggest that stimulant augmentation may be helpful in patients with an inadequate SRI response. However, stimulants may also induce OCD symptoms in some individuals (Jhanda *et al.* 2016). To confirm the efficacy of stimulants in patients with OCD and better understand their risk/benefit profile, rigorous testing in larger controlled studies is needed.

Combination Selective Serotonin Reuptake Inhibitor and Clomipramine

Another strategy that has been used in patients who did not obtain an adequate response to SSRI monotherapy is to combine an SSRI with clomipramine. This approach typically involves adding a low dosage of clomipramine (< 75 mg/day) to a maximum-dosage SSRI, with the goal of increasing the overall serotonergic effect while minimizing adverse effects that may occur with higher clomipramine dosages (Andrade 2013). This approach was reported to be effective in case series of both children and adolescents (Figueroa *et al.* 1998; Simeon *et al.* 1990) and adults (Browne *et al.* 1993) with SRI-refractory OCD. An open-label study in 24 adults with OCD that did not respond to initial treatment with clomipramine 150 mg/day found that adding sertraline 50 mg/day was more effective and better tolerated than increasing clomipramine to 250 mg/day (Ravizza *et al.* 1996). Similarly, another open-label study in 16 patients with OCD unresponsive to citalopram treatment found adding clomipramine to be more effective than continuing citalopram alone (Pallanti *et al.* 1999). In a third open-label trial, 20 patients with OCD with poor response to an SSRI and also to current treatment with clomipramine (mean dosage = 164 mg/day) were started on adjunct citalopram (mean dosage = 38 mg/day). Over the course of 48 weeks of treatment, Y-BOCS scores decreased by 30% on average and around half of patients were considered responders (Marazziti *et al.* 2008).

These open-label studies prompted a controlled trial in which 54 adult patients with OCD unresponsive to fluoxetine monotherapy were randomly assigned to clomipramine augmentation (maximum dosage = 75 mg/day), quetiapine augmentation (maximum dosage = 200 mg/day), or placebo. Fluoxetine was continued at 40 mg/day for participants in the active augmentation groups but increased to 80 mg in the placebo group. The participants who received quetiapine showed little improvement, whereas both the placebo group (with high-dosage fluoxetine) and the clomipramine group experienced a 25% decrease in Y-BOCS scores (Diniz *et al.* 2011). In contrast, another controlled trial by the same investigators did not find the combination of clomipramine and an SSRI to be effective; 21 adults whose symptoms did not respond to 12 weeks of SSRI treatment were continued on their SSRI and randomly assigned to augmentation with either clomipramine 75 mg/day or quetiapine. After 4 weeks of treatment, neither group showed significant improvement in OCD symptoms (Diniz *et al.* 2010).

When an SSRI and clomipramine are used in combination, their additive serotonergic effects may increase the risk of side effects, such as sexual dysfunction, QTc prolongation, seizures, and serotonin syndrome (Andrade 2013). Pharmacokinetic interactions may further increase this risk; for example, the cytochrome P450 (CYP) enzymes CYP1A2, CYP3A4, and CYP2C19 contribute to clomipramine's metabolism, whereas CYP2D6 is involved in metabolizing both clomipramine and its active metabolite desmethylclomipramine. SSRIs that inhibit these enzymes may therefore increase serum clomipramine levels and thus heighten the risk for adverse events. Fluoxetine, fluvoxamine, paroxetine, and to a lesser extent sertraline may all substantially elevate clomipramine levels, whereas studies of citalopram and escitalopram suggest that they have little effect on clomipramine levels (Taylor 1995). Conversely, clomipramine's inhibition of CYP2D6 may increase serum levels of SSRIs that are metabolized by this enzyme (fluoxetine, sertraline, paroxetine, citalopram, and escitalopram, but not fluvoxamine [Szegedi *et al.* 1996]). However, these effects may be less clinically significant when one considers that SSRIs are better tolerated than clomipramine and that most agents in this class are metabolized by several CYP enzymes in addition to CYP2D6 (Andrade 2013).

Overall, the evidence that favors combining an SSRI with clomipramine is too limited and the associated risks are too high to support the use of this strategy in most clinical scenarios. This approach may be helpful in some treatment-refractory cases, with the proviso that periodic monitoring of plasma levels and ECG results is important to avoid toxicity.

Other Augmentation Agents

Pindolol

Pindolol is an antihypertensive drug and antagonist of both b-adrenergic and 5-HT$_{1A}$ receptors, the latter of which are autoreceptors that decrease serotonin release when stimulated. By inhibiting 5-HT$_{1A}$ activity, pindolol may increase serotonin release and thus play a role in augmenting SRIs for OCD. To date, only two placebo-controlled studies of pindolol augmentation have been conducted in OCD: one in 15 adults with paroxetine-unresponsive symptoms (Dannon *et al.* 2000) and one in 16 adults with fluoxetine nonresponse (Mundo *et al.* 1998). The former (Dannon *et al.* 2000) reported that OCD symptoms were moderately more reduced following pindolol augmentation versus placebo, whereas the latter (Mundo *et al.* 1998) found no difference between pindolol and placebo. A subsequent meta-analysis including these studies and two earlier studies without placebo controls also failed to identify differences between pindolol and placebo, although only four studies were included (Sassano-Higgins and Pato 2015). Further research is needed before pindolol augmentation can be recommended in OCD treatment.

Buspirone

Buspirone, a 5-HT$_{1A}$ receptor partial agonist, is FDA approved for generalized anxiety disorder and showed early promise in a small controlled study in patients with OCD (Pato *et al.* 1991). However, a series of controlled trials subsequently found buspirone to have minimal effect on OCD symptoms (Jenike and Baer 1988; Markovitz *et al.* 1990; McDougle *et al.* 1993; Pigott *et al.* 1992). Thus, buspirone augmentation is not currently recommended in OCD treatment, although it may help some patients with comorbid anxiety disorders.

Serotonin Type 3A Receptor Antagonists

Three 5-HT$_{3A}$ receptor antagonists (ondansetron, granisetron, and tropisetron) have been tested as augmentation agents. These medications are widely used as antiemetics and, although not often prescribed in psychiatry, have garnered interest as potential OCD treatments because of their excellent safety profiles and ability to reduce OCD-like behaviors in some animal models (Serata *et al.* 2015). Ondansetron was initially tested as monotherapy in adults with OCD in two small controlled studies, with equivocal results (Broocks *et al.* 1998; Hewlett *et al.* 2003). Subsequent studies focused on augmentation approaches. In two small controlled OCD trials (n = 14 and 20), ondansetron 0.5-1 mg/day was added to ongoing SSRI treatment in adults whose symptoms had responded poorly to the initial treatment (Pallanti *et al.* 2009, 2014). Patient symptoms improved over the course of both 12-week trials; the second study also reported that two-thirds of responders experienced relapse in the 4 weeks after completing the protocol and stopping ondansetron (Pallanti *et al.* 2014). However, these studies used single-blinded designs (i.e., raters were aware of the study conditions) and lacked placebo controls.

The remainder of the 5-HT$_{3A}$ receptor antagonist trials have been conducted in Iranian patients. One study in adults with OCD randomly assigned participants to 8 weeks of treatment with either fluoxetine 20 mg/day and ondansetron 4 mg/day or fluoxetine and placebo (Soltani *et al.* 2010). A second trial with a similar design randomly assigned participants to either fluvoxamine 200 mg/day and ondansetron 8 mg/day or fluvoxamine and placebo (Heidari *et al.* 2014). Participants in both trials had larger symptomatic improvements with ondansetron augmentation than with placebo. Similar results were obtained in two trials in which adults with OCD were randomly assigned to treatment with fluvoxamine 200 mg/day and either a 5-HT$_{3A}$ receptor antagonist or placebo. One study used granisetron 2 mg/day (Askari *et al.* 2012), and the other used tropisetron 10 mg/day (Shalbafan *et al.* 2019). Finally, in a controlled trial in 135 patients whose symptoms had responded poorly to SSRIs, participants were randomly assigned to 14 weeks of augmentation with ondansetron, granisetron, or placebo (Sharafkhah *et al.* 2019). At week 14, participants in both active treatment groups had fewer symptoms than those in the placebo group, although the remission rate was higher in the ondansetron group. Although interesting, these findings should be interpreted with caution, considering that all five trials were conducted in the same geographic region. Indeed, a recent case series of 30 patients who received ondansetron augmentation in an Indian specialty clinic found that only 2 patients

showed response to this treatment, and nearly 80% discontinued the medication because of lack of efficacy (Kalyani *et al.* 2017). In the United States, a multisite randomized controlled trial of ondansetron augmentation was terminated because of a lack of efficacy (ClinicalTrials.gov 2013). Before 5-HT_3 antagonist augmentation can be recommended as an OCD treatment, controlled studies in more diverse populations are needed.

Additional Agents

Other agents, including lithium (McDougle *et al.* 1991; Pigott *et al.* 1991), the benzodiazepines alprazolam (Stein *et al.* 1992) and clonazepam (Crockett *et al.* 2004; Hollander *et al.* 2003c), thyroid hormone (Pigott *et al.* 1991), the tricyclic antidepressant desipramine (Hoehn-Saric *et al.* 2000; Leonard *et al.* 1989, 1991), the glutamate modulator mavoglurant (Rutrick *et al.* 2017), folic acid (Tural *et al.* 2019), and L-methylfolate (Dar *et al.* 2021), have also been tested as potential augmentation agents for OCD. Controlled trials of these medications have not revealed any convincing evidence that they are helpful when added to SRI treatment.

Emerging Combination/Augmentation Pharmacotherapies

Although current evidence-based pharmacotherapies for OCD are effective, some patients will continue to have clinically impairing symptoms despite an adequate dosage and trial duration, and a subset of this group will not achieve response. Given the need for more effective treatments, a variety of novel drugs are being investigated as potential monotherapies or combination/augmentation approaches. None of these agents have established efficacy for treating OCD symptoms, and some (e.g., ketamine) are typically delivered only in specialized settings. However, these approaches may be considered for patients whose symptoms respond poorly to the strategies described earlier.

Glutamate Modulators

Evidence that altered glutamate neurotransmission in the corticostriatal brain circuitry may contribute to OCD symptoms has led researchers to evaluate the use of glutamate modulators to augment SRI response in patients with treatment-resistant OCD (Pittenger *et al.* 2011). This line of research remains preliminary. However, several agents have shown early promise in small trials, as summarized next.

N-Acetylcysteine

N-Acetylcysteine (NAC) is a nutraceutical precursor of the amino acid cysteine that is involved in glutathione synthesis and is used in a variety of clinical situations, including as a mucolytic and to treat acetaminophen overdose (Couto and Moreira 2018). NAC's capacity to modulate glutamate neurotransmission and antioxidant properties led to studies of its potential to augment SRI treatment of OCD. Of the five randomized placebo-controlled NAC augmentation trials that have been conducted, three (two in adult patients [Afshar *et al.* 2012; Sarris *et al.* 2015] and one in children and adolescents [Ghanizadeh *et al.* 2017]) reported that patients receiving NAC augmentation showed modestly greater improvement in OCD symptoms compared with those receiving placebo. Another trial in adults (Paydary *et al.* 2016) found no significant difference in Y-BOCS scores between NAC and placebo, but patients who received NAC were more likely to achieve remission (i.e., Y-BOCS score [?] 16 at trial end). Finally, a study in adults (Costa *et al.* 2017) found no difference between NAC and placebo augmentation of SRI treatment. A recent meta-analysis reported that NAC augmentation showed mild to moderate benefit for OCD symptoms and no increased risk for adverse events compared with placebo (Gadallah *et al.* 2020). NAC dosing in these trials ranged from 600 to 3,000 mg/day, but most participants were treated with a dosage of 2,000-3,000 mg/day.

There remains a need for controlled trials of NAC in larger samples of patients with OCD. Nonetheless, NAC can be obtained without a prescription in the United States, has an excellent safety profile, and increasingly seems to have modest benefit in both adult and pediatric OCD populations when added to SSRIs (Gadallah *et al.* 2020). Given these factors, NAC is a reasonable starting point when considering augmentation with a glutamate modulator, particularly for children and adolescents.

Memantine

Several open-label and controlled trials also support memantine augmentation of SRIs. Memantine, which is FDA approved for treating Alzheimer's disease, is a noncompetitive *N*-methyl-D-aspartate (NMDA) receptor antagonist that may improve OCD symptoms by attenuating excessive glutamate signaling in corticostriatal circuitry (Modarresi *et al.* (2019). Initial open-label trials in both adults and children with OCD found some benefit from memantine augmentation of SSRIs (Aboujaoude *et al.* 2009; Feusner *et al.* 2009; Hezel *et al.* 2009; Rodriguez *et al.* 2016a; Stewart *et al.* 2010). Subsequently, multiple randomized placebo-controlled trials have reported moderate to large benefits from memantine augmentation in adults with OCD (Modarresi *et al.* (2018), including two with response rates of 93% and 100% (Ghaleiha *et al.* (2013; Haghighi *et al.* (2013). Another study found that memantine improved obsessions and compulsions that emerged during manic episodes in adult inpatients with bipolar disorder (Sahraian *et al.* (2017). Most of these studies used a memantine dosage of 20 mg/day. Side effects were generally mild and included fatigue and anxiety (Modarresi *et al.* (2019).

Although a recent meta-analysis supported the benefit of memantine augmentation in OCD (Modarresi *et al.* (2019), an additional randomized placebo-controlled trial in 99 adults with OCD found no difference between memantine and placebo (Farnia *et al.* 2018). Moreover, there are reasons to be skeptical of the large effects for memantine in the abovementioned studies. All four--Ghaleiha *et al.* (2013, Haghighi *et al.* (2013, Modarresi *et al.* (2018, and Sahraian *et al.* (2017)--had small sample sizes (*n* = 38, 29, 30, and 38, respectively) and were conducted in the same geographic region (Iran), which may limit their broader generalizability (Andrade 2019). Larger trials in more diverse populations are needed before memantine augmentation can definitively be considered effective in OCD treatment.

Riluzole

Riluzole is a glutamate modulator primarily used to treat amyotrophic lateral sclerosis and is thought to reduce glutamatergic neurotransmission through several mechanisms, including inhibiting glutamate release, inactivating voltage-gated sodium channels in cortical neurons, blocking GABA reuptake, and facilitating glutamate reuptake (Pittenger *et al.* 2008). A retrospective case series and an open-label trial (both in 13 adults with SSRI-resistant OCD) found that riluzole augmentation reduced OCD symptoms. More recently, two randomized placebo-controlled trials in patients with SSRI-resistant OCD (one in 22 adult outpatients and 11 adult inpatients and another in 59 children) both found no difference in OCD symptom reduction between riluzole and placebo (Grant *et* *al.* 2014; Pittenger *et al.* 2015). However, a third trial in 39 adults with SSRI-resistant OCD found that Y-BOCS scores were significantly more reduced with 8 weeks of riluzole augmentation compared with placebo (Emamzadehfard *et al.* 2016). Troriluzole, a riluzole prodrug, was also recently tested as an augmentation strategy in a large multicenter trial of adults with SRI-resistant OCD. No results are currently published, but press releases indicate that the study did not achieve its primary efficacy endpoint (Biohaven Pharmaceuticals 2020). The current evidence is insufficient to support riluzole augmentation in clinical treatment of OCD.

Topiramate

Topiramate is an antiepileptic drug that, like riluzole, modulates glutamate neurotransmission through several different mechanisms (Pittenger 2015). Two small open-label studies in adults with SSRI-resistant OCD found some benefit from topiramate augmentation (Rubio *et al.* 2006; Van Ameringen *et al.* 2006). Three randomized placebo-controlled trials were subsequently conducted in adults with SSRI-resistant OCD. One trial with 49 patients found significant benefit for topiramate augmentation over placebo (Mowla *et al.* 2010); a second trial with 36 patients reported that topiramate significantly improved compulsions, but not obsessions, compared with placebo (Berlin *et al.* 2011); and finally, a third trial with 38 patients found no difference between topiramate and placebo (Afshar *et al.* 2014). Topiramate was poorly tolerated across all three studies, with a number of participants dropping out due to adverse effects including paresthesias, fatigue, problems with memory and cognition, and kidney stones. Given its poor tolerability and limited data supporting its efficacy, topiramate augmentation cannot currently be recommended in OCD treatment.

Lamotrigine

Lamotrigine is an antiepileptic and mood-stabilizing drug that also has glutamate-modulating properties. Of two case series examining lamotrigine augmentation in patients with SSRI-resistant OCD, one found little evidence of symptomatic improvement over 4 weeks of treatment (Kumar and Khanna 2000), whereas a second found significant improvement in OCD symptoms and quality of life over 16 weeks (Hussain *et al.* 2015). A randomized placebo-controlled trial of lamotrigine augmentation (100 mg/day) in 33 adults with SSRI-resistant OCD found that it significantly improved OCD symptoms versus placebo over 16 weeks of treatment (Bruno *et al.* 2012). A similar trial in 53 adult patients treated for 12 weeks also found significant benefit for lamotrigine over placebo (Khalkhali *et al.* 2016). Lamotrigine was well tolerated in these studies; however, the high placebo response rates in both trials limit the conclusions that can be drawn. Further research in larger samples is needed to establish the efficacy of lamotrigine augmentation in the treatment of adult OCD.

Lamotrigine is FDA approved as a maintenance treatment for pediatric bipolar disorder and might have utility in the treatment of children and adolescents with OCD, but this has yet to be explored.

Gabapentin and Pregabalin

Gabapentin and pregabalin are glutamate modulators commonly used in the treatment of neuropathic pain, alcohol and benzodiazepine addiction, and anxiety. Both inhibit the activity of voltage-dependent calcium channels, leading to reduced glutamatergic neurotransmission, although pregabalin is at least three times more potent than gabapentin (Martinotti 2012). In an open-label study that randomly assigned 40 adults with OCD to either fluoxetine alone or fluoxetine combined with gabapentin, gabapentin augmentation seemed to increase the initial treatment response but performed no better than fluoxetine alone after 8 weeks (Onder *et al.* 2008). Somewhat better results have been achieved with pregabalin. A case series in 12 adults with SRI-resistant OCD found some benefit for pregabalin augmentation (Di Nicola *et al.* 2011). A small open-label trial in 10 adults with SRI-resistant OCD found significant improvement over 8 weeks of pregabalin augmentation (Oulis *et al.* 2011), and a randomized placebo-controlled trial in 56 patients reported that their SRI-resistant symptoms were significantly more reduced with pregabalin augmentation compared with placebo (Mowla and Ghaedsharaf 2020). Although the findings for pregabalin show some promise, there are too few data at this stage to evaluate the efficacy of either of these agents in augmenting SRI treatment of OCD.

Amantadine

Amantadine is an antiviral drug that was historically used for influenza prophylaxis but is now used to improve cognitive functioning in pediatric traumatic brain injury, Alzheimer's dementia, and Parkinson's disease (Grados *et al.* 2015). Mechanistically, amantadine both enhances presynaptic dopamine release and antagonizes the NMDA receptor. Two studies have examined its efficacy in augmenting SRI treatment of OCD. In the first, an open-label trial in eight adults whose OCD was unresponsive to at least one SSRI, patient symptoms improved significantly following 6 weeks of amantadine augmentation (Stryjer *et al.* 2014). The second was a controlled study in which unmedicated adults with moderate to severe OCD (i.e., Y-BOCS scores > 21) were randomly assigned to 12 weeks of fluvoxamine 200 mg/day and either placebo or amantadine 100 mg/day (Naderi *et al.* 2019). OCD symptoms improved in both treatment arms, although the group receiving amantadine augmentation experienced slightly greater reductions in OCD symptoms. However, this effect was small (< 3 points on the Y-BOCS) and of questionable clinical significance. Further research is needed to establish whether amantadine augmentation is truly effective.

Glycine

Glycine, an NMDA receptor agonist and glutamate-modulating amino acid, demonstrated potential as an anticompulsive agent in animal experiments and was subsequently tested in a small controlled trial (Kuygun Karci and Gul Celik 2020). Adult patients with SRI-refractory OCD (n = 24) were randomly assigned to 12 weeks of adjuvant glycine (60 mg/day) or placebo. Although some patients' symptoms improved, there was a high dropout rate in the glycine group because of nausea and complaints

about the taste, and there was no significant difference in outcome between groups (Greenberg *et al.* 2009).

Sarcosine

Sarcosine is an endogenous inhibitor of glycine reuptake that may increase the availability of synaptic glycine and thus enhance glutamate neurotransmission (Bergeron *et al.* 1998). In an open-label trial, 26 adults with OCD were treated with sarcosine flexibly dosed between 500 and 2,000 mg/day. Participants were drug naive (n = 8), free of serotonergic medication for at least 8 weeks (n = 6), or taking an SRI (n = 12); sarcosine was delivered as monotherapy in the former two groups and as an adjuvant in the latter (Wu *et al.* 2011). Although there was significant improvement in OCD symptoms across all groups, there were no between-group differences, and few conclusions can be drawn because of the broad inclusion criteria and lack of placebo control.

Ketamine

The NMDA receptor antagonist ketamine has generated interest in the field of psychiatry, owing to a growing literature suggesting that it can induce rapid-onset, long-lasting antidepressant effects (Kraus *et al.* 2019; Zarate *et al.* 2006). Initial case reports suggested that ketamine might have similar effects on OCD symptoms (Rodriguez *et al.* 2011), but subsequent findings have been mixed. An open-label trial of a single ketamine infusion in 10 adults with OCD found that symptoms of depression, but not OCD, improved over the following 3 days (Bloch *et al.* 2012). In contrast, a randomized controlled crossover trial in which 15 patients received both ketamine and placebo (separated by a week) reported that symptoms improved immediately after ketamine infusion and improvement was maintained in 50% of patients 1 week later (Rodriguez *et al.* 2013). Subsequent case series have examined the use of intranasal ketamine (Adams *et al.* 2017; Rodriguez *et al.* 2017) and attempted to extend the effects of intravenous ketamine with memantine (Rodriguez *et al.* 2016a) and CBT (Adams *et al.* 2017; Rodriguez *et al.* 2016b). In a chart review study of 14 adult inpatients with severe, SRI-unresponsive OCD, Y-BOCS scores decreased by at least 25% in 3 patients who received repeated ketamine dosing (average of 2-3 doses per week over 3 weeks), suggesting that repeated infusions could be helpful for a subset of patients with treatment-resistant symptoms (Sharma *et al.* 2020). Overall, the current data are too limited to fully evaluate ketamine's potential benefit in OCD; controlled studies in larger samples are needed.

Rapastinel (GLYX-13), an NMDA receptor glycine-site partial antagonist thought to have similar properties to ketamine, was also recently tested in a small controlled trial of unmedicated adults with severe OCD (Rodriguez *et al.* 2016c). Whereas ketamine was associated with adverse effects including dissociation, dizziness, nausea, and vomiting, rapastinel was well tolerated in this sample. Although OCD symptoms improved in the initial 3 hours after treatment for a subset of patients, these improvements were not sustained at 1-week follow-up.

Anti-Inflammatories

An expanding literature links inflammation and abnormal immunological function to OCD symptoms (Gerentes *et al.* 2019). Interest in the relationship between autoimmunity and OCD began in the 1990s, with the description of pediatric acute neuropsychiatric disorders associated with streptococcal infection (PANDAS [Swedo *et al.* 1998]), a syndrome in which neuropsychiatric symptoms including tics, obsessions, and compulsions occur suddenly in patients with a history of group A Streptococcus infections. This category has since been subsumed by the umbrella category pediatric acute neuropsychiatric syndrome (PANS), which includes cases of rapid-onset OCD symptoms that are not preceded by infection (Swedo *et al.* 2012). Research has extended the proposed relationship between inflammatory/autoimmune processes and OCD to include adults, with recent data revealing abnormal inflammatory markers in the corticostriatal brain circuitry implicated in OCD (Attwells *et al.* 2017). There have also been several recent trials of anti-inflammatory agents as potential treatments for OCD symptoms.

Minocycline

Minocycline is a tetracycline antibiotic that has garnered interest as a potential OCD treatment due to its combination of anti-inflammatory and glutamate-modulating properties (Rodriguez *et al.* 2010). In an initial open-label trial in nine adults with SRI-resistant OCD, minocycline 200 mg/day was added to ongoing SRI treatment but did not yield significant symptomatic improvement over 12 weeks (Rodriguez *et al.* 2010). In contrast, a randomized controlled trial in which 102 unmedicated adults with OCD were treated with 10 weeks of fluvoxamine 200 mg/day and either minocycline 200 mg/day or placebo reported significantly greater improvement in obsessions, but not compulsions, among those who received minocycline (Esalatmanesh *et al.* 2016). However, the overall benefit of minocycline was quite small, and further research is needed to determine whether this effect can be replicated.

Celecoxib

Celecoxib is a nonsteroidal anti-inflammatory drug (NSAID) that inhibits the cyclooxygenase-2 enzyme and is approved in the United States for the treatment of arthritis and other inflammatory conditions (Grassi and Pallanti 2018). Two randomized controlled trials added celecoxib 400 mg/day versus placebo augmentation to ongoing treatment with an SSRI (either fluoxetine 20 mg/day or fluvoxamine 200 mg/day) in adults with OCD; both found greater symptomatic improvement with celecoxib augmentation over placebo across 8 weeks of treatment (Sayyah *et al.* 2011, *n* = 25; Shalbafan *et al.* 2015, *n* = 50). Study design issues, including the low SSRI dosages used and an insufficient treatment period before adding celecoxib, complicate interpretation of these results. Two additional studies of celecoxib augmentation in patients with OCD (one in adults [https://clinicaltrials.gov/study/NCT04786548] and one in children [https://clinicaltrials.gov/study/NCT04673578]) are listed as ongoing on ClinicalTrials.gov but have yet to post results.

Nonsteroidal Anti-Inflammatory Drugs

The role of NSAIDs as a class was examined in a retrospective chart review of 77 children meeting PANS criteria who received these agents for arthritis, pain, or psychiatric symptoms (Spartz *et al.* 2017). Results suggested that neuropsychiatric symptoms improved in roughly a third of patients, with mild gastrointestinal symptoms being the most common side effect. No controlled studies of NSAIDs in the treatment of PANS have been conducted, limiting the conclusions that can be drawn.

Antibiotics

Evidence of an association between bacterial infections and neuropsychiatric symptoms (including OCD symptoms) led to the hypothesis that antibiotics might reduce OCD symptoms in these cases (Burchi and Pallanti 2018). To date, only three trials have tested this possibility, with mostly negative results. The first was a randomized double-blind, placebo-controlled crossover study in 37 children with PANDAS, which did not show any benefit to OCD symptoms or tics with 4 months of penicillin prophylaxis compared with placebo (Garvey *et al.* 1999). The second was a randomized double-blind, placebo-controlled trial of azithromycin in 31 children with PANS (of whom 19 met PANDAS criteria) over 4 weeks (Murphy *et al.* 2017). The investigators found that CY-BOCS scores did not differ between the azithromycin and placebo groups, although overall severity on the Clinical Global Impression Scale was significantly lower among those who received azithromycin. Finally, a third study evaluated the effects of 30 days of treatment with the cephalosporin antibiotic cefdinir in 20 children with recent-onset OCD symptoms or tics, who were not required to have a history of infection or meet PANS criteria. The investigators found no differences in either OCD symptoms or tics among those who received cefdinir versus placebo (Murphy *et al.* 2015). These study results are challenging to interpret, considering their small size and the heterogeneity of their associated populations and designs. Although further study is warranted, the current literature provides little evidence that antibiotics are effective in treating PANS or OCD symptoms.

Opiates

A few studies have examined the use of modulators of the m opioid receptor in patients with SRI-resistant OCD. In one open-label trial, seven adults with OCD refractory to SRIs underwent a medication washout and were then treated with tramadol ([?] 400 mg/day). OCD symptoms decreased by 26% over the 6-week trial (Shapira *et al.* 1997). A later study evaluated the effects of augmenting SRIs with morphine, which lacks tramadol's serotonin/norepinephrine reuptake inhibition and is 6,000 times more potent at the m opioid receptor (Koran *et al.* 2005a). In a within-subjects design, 23 adults with SRI-refractory OCD completed three 2-week study blocks in which they received once-weekly oral morphine (15-45 mg), lorazepam (0.5-2 mg), or placebo. Morphine led to significantly greater improvement in OCD symptoms than either lorazepam or placebo (Koran *et al.* 2005a). Finally, a randomized placebo-controlled trial examined the effects of augmenting SRIs with the partial m opioid receptor agonist buprenorphine. In 43 adults whose OCD symptoms were SRI unresponsive, buprenorphine augmentation led to a faster decline in symptoms than placebo but did not differ in its effect on Y-BOCS scores over the course of 12 weeks (Ahmadpanah *et al.* 2017). The findings for each of these opiates are intriguing, but they require rigorous testing in larger trials before any conclusions can be drawn.

Tolcapone

Tolcapone is a selective, reversible inhibitor of the enzyme catechol O-methyltransferase that is FDA approved as an adjuvant to levodopa-carbidopa therapy for Parkinson's disease (Enna and Bylund 2011). Given its capacity to enhance dopaminergic signaling, a recent randomized double-blind, placebo-controlled crossover trial examined the effects of 2 weeks of tolcapone treatment in 20 adults with OCD (Grant *et al.* 2021b). Tolcapone led to modest but significant improvements in OCD symptoms over placebo, supporting its further investigation by future studies in patients with OCD.

Psilocybin

In the past decade, there has been a resurgence of interest in the therapeutic applications of psychedelics for various psychiatric conditions (Lieberman and Shalev 2016). In OCD, the serotonergic psychedelic psilocybin has garnered particular attention (Wilcox 2014) and so far is the only psychedelic drug to receive substantial research attention. Psilocybin is a component of various fungal species, including the *Psilocybe cubensis* mushroom (Halberstadt *et al.* 2018). When ingested, psilocybin is converted into the lipid-soluble psilocin, which rapidly crosses the blood-brain barrier and is thought to be responsible for its psychoactive effects (Jacobs 2020). Psilocin is active at a number of receptors in the brain but has high affinity for 5-HT$_{1A}$, 5-HT$_{2A}$, and 5-HT$_{2C}$ receptors (Halberstadt *et al.* 2018). The characteristic psychedelic effects of psilocybin include altered perception and cognition and are thought to be due to 5-HT$_{2A}$ agonism in particular (Carhart-Harris *et al.* 2011). Psilocybin has also been associated with increased expression of brain-derived neurotrophic factor (which is thought to play a role in neurogenesis and have neuroprotective effects), modulation of glutamate signaling, and transient increases in global connectivity throughout the brain, all of which are hypothesized to relate to its purported therapeutic benefits (Jacobs 2020).

Psilocybin was tested in patients with OCD in a small open-label trial in 2006 (Moreno *et al.* 2006). Nine adults with OCD received increasing single doses of psilocybin ([?] 300 mcg/kg), each separated by at least a week, with a single low dose (25 mcg/kg) administered at a random time point after the first dose. Participants were monitored over the next 8 hours and again at 24 hours postingestion. Psilocybin was well tolerated, and all participants reported symptomatic improvement after receiving psilocybin.

However, the effects were not dose dependent, and, in fact, four participants reported substantial improvement after receiving the 25-mcg/kg dose, which was intended to be a placebo comparator (Moreno *et al.* 2006). Although intriguing, this study was limited by design issues, including a small sample size and lack of a true placebo. There is also debate concerning how best to deliver psilocybin, with some suggesting that its effects may depend on facilitating psychotherapy (e.g., by enhancing openness to change and/or acceptance of emotional experience) and others stating that its effects are primarily pharmacological in nature (Jacobs 2020).

Agomelatine

Agomelatine is a novel medication that is approved as an antidepressant in Europe and Australia but is not currently FDA approved in the United States. Agomelatine acts as both an antagonist of the 5-HT$_{2B}$ and 5-HT$_{2C}$ receptors and an agonist of the melatonin MT$_1$ and MT$_2$ receptors; synergy between these effects is also thought to increase dopamine and norepinephrine levels in the prefrontal cortex and to promote cortical and hippocampal expression of brain-derived neurotrophic factor (Martinotti *et al.* 2016). This unique mechanistic profile has garnered greater interest in agomelatine as a possible treatment for sleep disturbances that occur in the setting of psychiatric illness.

Particular interest in agomelatine's potential role in treating OCD has recently developed in light of evidence that circadian rhythm abnormalities are much more common in

OCD than in the general population (estimated range, 17%-42% vs. 1%-10%, respectively [Nota *et al.* 2015]) and that these abnormalities are correlated with OCD symptom severity (Mukhopadhyay *et al.* 2008; Turner *et al.* 2007) and responsiveness to treatment (Donse *et al.* 2017). Although controlled studies have not been conducted, a recent case series including 10 adults with OCD who were treated with agomelatine showed that symptoms improved in all 7 patients who reported pretreatment sleep disturbances, with a reduction in Y-BOCS scores ranging from 46% to 90%. In contrast, Y-BOCS scores showed little to no change among those who did not report sleep disturbances (Coles and Goodman 2020). Although they are too preliminary to support clinical use at this stage, these encouraging findings suggest that controlled trials of agomelatine for treating individuals with OCD and comorbid sleep disturbances are warranted.

Nutraceuticals

Nutraceuticals (i.e., food products, herbs, and other dietary supplements thought to have health benefits) with serotonergic, antioxidant, anti-inflammatory, and/or glutamate-modulating properties have also been evaluated as either standalone or adjuvant therapies for treating OCD symptoms (Kuygun Karci and Gul Celik 2020). Agents tested to date and relevant information from the studies in which they were evaluated are summarized in Table 52-3. Of the agents tested, the most promising may be the dietary elements zinc and selenium--the serum levels of which were found to be lower in adults with OCD (Ozdemir *et al.* 2009; Shohag *et al.* 2012). Two augmentation studies found small but significant reductions in Y-BOCS scores when zinc (Sayyah *et al.* 2012a) and selenium (Sayyah *et al.* 2018) were added to ongoing SRI treatment compared with placebo. A recent open-label study reported on a nutraceutical formulation that included both zinc and selenium, along with NAC, L-theanine, and pyridoxal 5'-phosphate, in 20 adults with OCD unresponsive to prior SRI treatment. The combined formula containing multiple nutraceuticals as an adjuvant to SRI treatment was associated with a significant reduction in Y-BOCS scores over 20 weeks, although response was greatest among those with less severe symptoms at baseline and was minimal among those with more severe symptoms (Sarris *et al.* 2022).

TABLE 52-3. Nutraceuticals tested in patients with obsessive-compulsive disorder

Agent	Putative mechanism	Studies	Design	Sample	Key findings
Myoinositol	Thought to modulate 5-HT reuptake and increase 5-HT receptor density (Kuygun Karci and Gul Celik 2020)	1) Carey *et al.* 2004	1) 6-week randomized double-blind, placebo-controlled crossover study of inositol monotherapy	1 and 2) Adults with OCD (*n* = 13 and 14)	1) Significantly greater reduction in Y-BOCS scores with inositol (18 g) over placebo
		2) Fux *et al.* 1996	2) 12-week open-label trial of inositol monotherapy	2) Significant reduction in Y-BOCS over 12 weeks of inositol (18 g) treatment	
		3) Fux *et al.* 1999	3) 6-week randomized double-blind, placebo-controlled crossover study of inositol augmentation of SRI	3 and 4) Adults with OCD unresponsive to SRIs (*n* = 10, both studies)	3) No between-group difference in Y-BOCS
4) Seedat and Stein 1999	4) 6-week open-label trial of inositol augmentation of SRI	4) No significant change in Y-BOCS or Clinical Global Impression Scale scores			
5-Hydroxy-tryptophan	Nonessential amino acid; precursor to	Yousefzadeh *et al.* 2020	Randomized double-blind, placebo-	Adults with OCD (*n* = 60)	Small but significant Y-BOCS reduction

Note. 5-HT = 5-hydroxytryptamine (serotonin); MAO = monoamine oxidase; NAC = *N*-acetylcysteine; SRI = serotonin reuptake inhibitor; SSRI = selective serotonin reuptake inhibitor; Y-BOCS = Yale-Brown Obsessive Compulsive Scale.

Agent	**Putative mechanism**	**Studies**	**Design**	**Sample**	**Key findings**
	5-HT (Kuygun Karci and Gul Celik 2020)		controlled trial of 5-hydroxytryptophan augmentation (200 mg/day)		for 5-hydroxytryptophan vs. placebo augmentation of fluvoxamine (20 mg/day for 4 weeks before study, then [?] 60 mg/day)
Limitations: submaximal fluvoxamine dosage, inadequate fluvoxamine pretreatment					
St. John's wort (*Hypericum perforatum*)	Inhibition of MAO A/B and of 5-HT, norepinephrine, and dopamine reuptake (Camfield *et al.* 2011)	1) Kobak *et al.* 2005	1) 12-week open-label trial of St. John's wort monotherapy (900 mg/day)	1) Adults with OCD (*n* = 12)	1) Significant Y-BOCS reduction over 12 weeks
2) Taylor and Kobak 2000	2) 12-week randomized double-blind, placebo-controlled trial of St. John's wort monotherapy (600-1,800 mg/day)	2) Adults with OCD (*n* = 60)	2) No difference in Y-BOCS for St. John's wort vs. placebo		

Note. 5-HT = 5-hydroxytryptamine (serotonin); MAO = monoamine oxidase; NAC = *N*-acetylcysteine; SRI = serotonin reuptake inhibitor; SSRI = selective serotonin reuptake inhibitor; Y-BOCS = Yale-Brown Obsessive Compulsive Scale.

Agent	**Putative mechanism**	**Studies**	**Design**	**Sample**	**Key findings**
Saffron (*Crocus sativus* L.) and crocin (active component of saffron)	Poorly understood; may have anxiolytic, antidepressant, and/or neuroprotective properties (Ayati *et al.* 2020)	1) Esalatmanesh *et al.* 2017	1) 10-week randomized controlled trial of saffron (30 mg/day) vs. fluvoxamine (100 mg/day)	1) Unmedicated adults with mild to moderate OCD (Y-BOCS range, 12-21; *n* = 50)	1) Y-BOCS decreased in both groups; no between-group differences
		2) Kazemi *et al.* 2021	2) 8-week randomized controlled trial of crocin (15 mg) vs. fluoxetine (20 mg)	2) Unmedicated adults with mild to moderate OCD (Y-BOCS range, 12-25; *n* = 50)	2) Y-BOCS decreased in both groups; no between-group differences
			Limitations: lack of placebo control, inadequate SRI dosage and trial duration		
Ashwaganda *(Withania somnifera)*	Properties may include anti-inflammatory and antioxidant effects, cholinesterase inhibition (Chengappa *et al.* 2013)	Jahanbakhsh *et al.* 2016	6-week randomized double-blind, placebo-controlled trial of ashwaganda extract (120 mg/day) augmentation of ongoing SSRI treatment	Adults with OCD currently taking an SSRI (*n* = 30)	Significantly greater reduction in Y-BOCS scores for ashwaganda vs. placebo (12 vs. 8 points, respectively)
Limitations: small sample, short trial duration; baseline Y-BOCS was 8					

Note. 5-HT = 5-hydroxytryptamine (serotonin); MAO = monoamine oxidase; NAC = *N*-acetylcysteine; SRI = serotonin reuptake inhibitor; SSRI = selective serotonin reuptake inhibitor; Y-BOCS = Yale-Brown Obsessive Compulsive Scale.

Agent	Putative mechanism	Studies	Design	Sample	Key findings
points lower in ashwaganda group than in placebo group					
Milk thistle *(Silybum marianum)*	Poorly understood; may have antioxidant and anti-inflammatory properties; increases cortical serotonin and/or MAO inhibition (Kuygun Karci and Gul Celik 2020)	Sayyah *et al.* 2010	8-week randomized controlled trial of milk thistle extract (600 mg/day) vs. fluoxetine (30 mg/day)	Unmedicated adults with OCD (*n* = 35)	Y-BOCS scores decreased in both groups; no between-group differences
Limitations: small sample, inadequate fluoxetine dosage and trial duration					
Valerian root (*Valeriana officinalis* L.)	Poorly understood; may have GABAergic properties (Kuygun Karci and Gul Celik 2020)	Pakseresht *et al.* 2011	8-week randomized double-blind, placebo-controlled trial of valerian extract (675 mg/day) vs. placebo	Unmedicated adults with OCD (*n* = 31)	Y-BOCS scores decreased in both groups; small but statistically significant increase in improvement for valerian vs. placebo Somnolence was greater in valerian group
Limitations: small sample					

Note. 5-HT = 5-hydroxytryptamine (serotonin); MAO = monoamine oxidase; NAC = *N*-acetylcysteine; SRI = serotonin reuptake inhibitor; SSRI = selective serotonin reuptake inhibitor; Y-BOCS = Yale-Brown Obsessive Compulsive Scale.

Agent	Putative mechanism	Studies	Design	Sample	Key findings
size, short trial duration, lack of comparison to evidence-based treatment, clinical meaningfulness of small treatment effect unclear					
Borage (*Echium amoenum*)	Poorly understood; may have anxiolytic and/or antidepressant properties (Sarris *et al.* 2011)	Sayyah *et al.* 2009	6-week randomized double-blind, placebo-controlled trial of borage extract (500 mg/day) vs. placebo	Unmedicated adults with OCD (*n* = 44)	Y-BOCS scores decreased in both groups; small but statistically significant increase in improvement for borage vs. placebo
Limitations: small sample size, short trial duration, lack of comparison to evidence-based treatment, clinical meaningfulness of small treatment effect unclear					
Zinc	Dietary element; serum levels may be decreased in OCD	Sayyah *et al.* 2012a	6-week randomized double-blind, placebo-controlled trial of zinc (440 mg/day) or placebo	Unmedicated adults with OCD (*n* = 23)	Y-BOCS scores decreased in both groups; small but statistically significant increase in improvement for

Note. 5-HT = 5-hydroxytryptamine (serotonin); MAO = monoamine oxidase; NAC = *N*-acetylcysteine; SRI = serotonin reuptake inhibitor; SSRI = selective serotonin reuptake inhibitor; Y-BOCS = Yale-Brown Obsessive Compulsive Scale.

Agent	**Putative mechanism**	**Studies**	**Design**	**Sample**	**Key findings**
	(Shohag *et al.* 2012)		augmentation of fluoxetine (20 mg/day)		zinc vs. placebo augmentation
Limitations: small sample size, short trial duration, clinical meaningfulness of small treatment effect unclear, no control for dietary sources of zinc					
Selenium	Dietary element; serum levels may be decreased in OCD (Ozdemir *et al.* 2009)	Sayyah *et al.* 2018	6-week randomized double-blind, placebo-controlled trial of selenium (200 mg/day) or placebo augmentation of ongoing SRI treatment	Adults with OCD unresponsive to ongoing SSRI treatment (*n* = 32)	Y-BOCS scores decreased in both groups; small but statistically significant increase in improvement for selenium vs. placebo augmentation
Limitations: small sample size, short trial duration, clinical meaningfulness of small treatment effect unclear, no control for dietary sources of selenium					

Note. 5-HT = 5-hydroxytryptamine (serotonin); MAO = monoamine oxidase; NAC = *N*-acetylcysteine; SRI = serotonin reuptake inhibitor; SSRI = selective serotonin reuptake inhibitor; Y-BOCS = Yale-Brown Obsessive Compulsive Scale.

Agent	Putative mechanism	Studies	Design	Sample	Key findings
Nutraceutical combination	Multiple	Sarris *et al.* 2022	20-week open-label trial of a nutraceutical formulation containing NAC, L-theanine, zinc, magnesium, pyridoxal 5'-phosphate, and selenium as augmentation of ongoing SSRI treatment	Adults with OCD unresponsive to ongoing SSRI treatment (*n* = 20)	Y-BOCS scores decreased by a mean of 7.13 over the course of the trial; 23% of participants were considered responders (i.e., Y-BOCS decrease [?] 35%) Effects were greatest in those with lowest baseline Y-BOCS scores; minimal response in those with more severe symptoms
Limitations: small sample size, high dropout rate, lack of placebo control					

Note. 5-HT = 5-hydroxytryptamine (serotonin); MAO = monoamine oxidase; NAC = *N*-acetylcysteine; SRI = serotonin reuptake inhibitor; SSRI = selective serotonin reuptake inhibitor; Y-BOCS = Yale-Brown Obsessive Compulsive Scale.

These findings should be considered preliminary at best, considering that all of the studies included small samples and most had significant design flaws that limit their interpretation. As a result, none of the nutraceuticals summarized here can be recommended for patients with OCD in most clinical situations. Nonetheless, nutraceuticals are often easier to access and present relatively few risks compared with prescription medications, and they are thus of great interest to patients and clinicians alike. Further research in well-designed controlled trials is warranted to determine whether any of these agents is effective in patients with OCD.

Pharmacological Augmentation of Exposure and Ritual Prevention Cognitive-Behavioral Therapy

CBT consisting of exposure and ritual prevention (EXRP) is well established as a treatment for OCD, and the strong evidence supporting its efficacy has led to its recommendation as a first-line therapy (Foa *et al.* 1984; Franklin *et al.* 2000; Koran *et al.* 2007; Simpson *et al.* 2013). Nonetheless, fewer than half of patients who receive a full course of EXRP will achieve remission (Farris *et al.* 2013; Simpson *et al.* 2006, 2008, 2021). Recognizing this limitation, there have been a variety of attempts to use medications to enhance the effectiveness of EXRP. The agents that have been tested generally affect neurocognitive functions that are supported by CBT and the brain circuits that subserve them (Patel *et al.* 2021). These functions include fear processing (e.g., extinction learning and recall, safety learning, memory reconsolidation [Fullana *et al.* 2020]) and cognitive control (McTeague *et al.* 2017; Wheaton *et al.* 2016). Studies of agents tested as potential pharmacological enhancers of CBT are summarized next.

D-Cycloserine

D-Cycloserine is a partial NMDA receptor agonist shown in animal studies to enhance both synaptic plasticity and the associative learning processes involved in fear extinction (Kaplan and Moore 2011). Interest in the potential of D-cycloserine to facilitate human fear extinction increased after an initial proof-of-concept study in patients with height phobia reported that D-cycloserine improved outcomes when added to exposure treatment (Ressler *et al.* 2004). Since then, at least eight randomized controlled trials have compared EXRP monotherapy against EXRP in combination with D-cycloserine among either adults or children with OCD. Of the four adult studies, two found that D-cycloserine increased the initial response rate but ultimately did not lead to greater symptomatic improvement than EXRP alone (Kushner *et al.* 2007; Wilhelm *et al.* 2008), whereas three others found no benefit from D-cycloserine augmentation (Andersson *et al.* 2015; de Leeuw *et al.* 2017; Storch *et al.* 2007). Similarly, one study of D-cycloserine augmentation in children with treatment-resistant OCD found that it improved EXRP outcomes at 1-month follow-up (Farrell *et al.* 2013) but showed no difference at 3-month follow-up, whereas two other studies in this population found no between-group differences in outcome (Mataix-Cols *et al.* 2014; Storch *et al.* 2016). More recently, four separate meta-analyses found that D-cycloserine augmentation had minimal effects on OCD symptoms (Burkner *et al.* 2017; Mataix-Cols *et al.* 2017; McGuire *et al.* 2017; Xia *et al.* 2015). Secondary analyses of pooled data from 21 studies of D-cycloserine augmentation of exposure treatment for OCD and other conditions suggest that inconsistencies in the timing and number of doses used in these studies may contribute to the lack of observed efficacy, suggesting that further research is warranted (Rosenfield *et al.* 2019). Nonetheless, the current literature provides insufficient support to recommend D-cycloserine augmentation of EXRP in clinical practice.

Ketamine

Rodent studies suggesting that ketamine can promote synaptic plasticity (Gideons *et al.* 2014; Liu *et al.* 2012) and facilitate extinction learning (Duman 2014) prompted a small open-label trial of its use to augment EXRP in adults with OCD. Unmedicated adults with OCD (*n* = 10) received intravenous ketamine, followed by 10 EXRP sessions delivered in the 2-week interval after ketamine administration when its effects on fear extinction are thought to be greatest. Results suggested that ketamine rapidly improved obsessions, and that its combination with EXRP had better efficacy than either

treatment alone (Rodriguez *et al.* 2016b). Although intriguing, these preliminary findings have yet to be evaluated in randomized controlled trials.

Cannabinoids

Agents that modulate the brain's endocannabinoid system (i.e., cannabinoids) have also been tested as potential facilitators of exposure-based treatment, including in OCD (Kayser *et al.* 2019). The idea that cannabinoids might enhance EXRP treatment stems from convergent preclinical evidence that these agents can attenuate excessive threat responding (Phan *et al.* 2008; Rabinak *et al.* 2020), facilitate extinction learning and/or recall (Hammoud *et al.* 2019; Rabinak *et al.* 2013, 2014, 2018), and/or promote an appropriate balance between goal-directed and habitual behaviors (Gianessi *et al.* 2020, 2022; Gremel *et al.* 2016). Cannabinoid augmentation of EXRP was recently investigated in a small trial in 11 unmedicated adults with OCD (Kayser *et al.* 2020). Participants were randomly assigned to 4 weeks of either monotherapy with nabilone (a synthetic analog of D-9-tetrahydrocannabinol, the primary psychoactive component of the cannabis plant and a partial agonist at the cannabinoid CB_1 receptor) or nabilone combined with nine sessions of EXRP. A separate group of patients received 4 weeks of EXRP alone. Participants who received nabilone alone showed little improvement, whereas those who received nabilone with EXRP improved nearly twice as much as those in the comparison sample who received EXRP alone (Kayser *et al.* 2020). As with ketamine, nabilone augmentation of EXRP needs to be evaluated in larger randomized controlled trials before it can be recommended in clinical practice. Nabilone's engagement with the fear network and its other putative mechanistic targets must also be confirmed in mechanistic studies.

Neuromodulation and Neurosurgical Approaches

Neuromodulation involves delivering targeted stimulation to key brain regions in order to modulate activity within distinct neural circuits. These approaches, developed and refined over the past two decades, may offer greater specificity than most pharmacotherapies. The intensity of neuromodulation can be adjusted in many cases to enable flexible "dosing," while the reversibility of these approaches may mitigate their potential for adverse effects (Bais *et al.* 2014). Although a detailed discussion of these approaches is beyond the scope of this chapter, we will provide an overview of key findings regarding the safety and efficacy of neuromodulation in OCD treatment.

Electroconvulsive Therapy

Although electroconvulsive therapy was widely used in OCD treatment until the mid-1980s, it has fallen out of favor due to safety concerns and equivocal data regarding efficacy (Bais *et al.* 2014). Several case reports and case series suggest that electroconvulsive therapy may benefit selected patients with severe, treatment-resistant OCD symptoms (often with comorbid depression), but this has not been tested in controlled trials (Dos Santos-Ribeiro *et al.* 2018). As a result, electroconvulsive therapy is rarely used to treat OCD in clinical practice today and is recommended only for patients with comorbid conditions that are likely to be responsive (e.g., severe depression).

Transcranial Magnetic Stimulation

Transcranial magnetic stimulation (TMS) is a noninvasive technique in which pulses of electricity are passed through a coil placed over the head, inducing a magnetic field that modulates excitability within targeted cortical regions (Bais *et al.* 2014). The degree of excitability varies with the frequency of the stimulation, with high-frequency stimulation (5-20 Hz) increasing and low-frequency stimulation (0-5 Hz) decreasing neuronal activity. Because TMS only transiently alters activity in the targeted brain circuits, repetitive administration (i.e., repetitive transcranial magnetic stimulation [rTMS]) is required to produce longer-term effects (Bais *et al.* 2014).

rTMS studies have focused on stimulating brain regions and circuits in which abnormal function has been linked to OCD symptoms. These include the supplemental motor area (SMA), the dorsolateral prefrontal cortex (dlPFC), and the orbitofrontal cortex (OFC). The SMA is involved in higher-order motor control and coordinating sequential motor actions and is thought to be hyperactive in OCD, which may contribute to compulsive behaviors (Mantovani *et al.* 2010). The dlPFC is broadly involved in executive functions that coordinate goal-directed behaviors, which include working memory, planning, and control over affective, attentional, and sensorimotor processes (Shephard *et al.* 2021). dlPFC hypoactivity is thought to contribute to clinical impairments seen in patients with OCD, including pathological doubt, compulsive checking, and deficient emotion regulation. The OFC is thought to moderate reward-associated learning and decision-making. Aberrant OFC activity during reward processing is thought to underlie aberrant reward processing that has been observed in patients with OCD (Kaufmann *et al.* 2013) and may contribute to compulsive behaviors. Table 52-4 summarizes the results of rTMS studies targeting each of these regions. Overall, only OFC-targeted rTMS has consistently been found to reduce OCD symptoms in controlled studies; results from trials targeting the dlPFC and SMA have been mixed.

TABLE 52-4. Neuromodulation and neurosurgical approaches

Role in treatment	Clinical considerations	Supporting research
Electroconvulsive therapy (ECT)		
Not recommended in most clinical situations	Case reports suggest some potential benefit for patients with OCD and severe comorbid depression, but this has not been tested in controlled trials.	Bais *et al.* 2014
ECT is generally not recommended in OCD because of the lack of evidence of efficacy and risk for impaired cognition and other side effects.	Dos Santos-Ribeiro *et al.* 2018	
Transcranial magnetic stimulation (TMS)		

Note. DBS = deep brain stimulation; dTMS = deep transcranial magnetic stimulation; OFC = orbitofrontal cortex; SMA = supplemental motor area; SRI = serotonin reuptake inhibitor; Y-BOCS = Yale-Brown Obsessive Compulsive Scale.

Role in treatment	Clinical considerations	Supporting research
May have some benefit in patients with symptoms unresponsive to > 1 SRI trial	A noninvasive technique in which a magnetic field modulates excitability within targeted brain regions.	Carmi *et al.* 2019
	Only dTMS has consistently shown benefit for OCD and is FDA approved.	McCathern *et al.* 2020
	dTMS targeting the medial prefrontal cortex and dorsal anterior cingulate cortex was shown to be more effective than sham TMS in controlled studies when paired with personalized symptom provocations; there is currently no evidence that dTMS is effective if not delivered alongside provocations.	Roth *et al.* 2021
Side effects include localized scalp discomfort, muscle twitches, lightheadedness, and headaches; serious side effects are rare and include seizures and hearing loss (can be mitigated by using earplugs).		
Neurosurgery		
As a last resort in severe, treatment-refractory cases	In a systematic review, ablative procedures (e.g., cingulotomy and anterior capsulotomy) led to improvement in 25%-50% of patients with severe, treatment-refractory OCD.	Denys *et al.* 2010
	Ablative procedures were generally well tolerated but should be pursued only as a last resort because of their irreversible nature.	Hageman *et al.* 2021
	DBS involves implanting a small electrode in the brain, usually in the region of the bed nucleus of the stria terminalis and nucleus accumbens.	Luyten *et al.* 2016
	DBS may be a potentially reversible alternative, and was recently granted a humanitarian exemption by the FDA.	Pepper *et al.* 2015
DBS led to an average acute Y-BOCS score reduction of 40% among patients with treatment-refractory OCD in recent controlled trials, but its long-term effects remain unclear.	Wu *et al.* 2021	
Other neuromodulation approaches		

Note. DBS = deep brain stimulation; dTMS = deep transcranial magnetic stimulation; OFC = orbitofrontal cortex; SMA = supplemental motor area; SRI = serotonin reuptake inhibitor; Y-BOCS = Yale-Brown Obsessive Compulsive Scale.

Role in treatment	**Clinical considerations**	**Supporting research**
Current evidence insufficient to recommend in clinical practice	Transcranial direct current stimulation to the SMA and OFC showed promise in early trials; transcranial alternate current stimulation is also under investigation.	da Silva *et al.* 2021
	Magnetic seizure therapy, in which magnetic fields are used to induce localized seizure activity, was not shown to be effective in a small study.	Germann *et al.* 2021
	A small case series suggested that ultrasound capsulotomy may be a noninvasive alternative to ablative neurosurgery, but controlled studies are needed.	Gowda *et al.* 2019
	Tang *et al.* 2021	

Note. DBS = deep brain stimulation; dTMS = deep transcranial magnetic stimulation; OFC = orbitofrontal cortex; SMA = supplemental motor area; SRI = serotonin reuptake inhibitor; Y-BOCS = Yale-Brown Obsessive Compulsive Scale.

Recently, more elaborate coils have been developed that can generate magnetic pulses over a larger area and with deeper penetrance. Deep transcranial magnetic stimulation (dTMS) uses this technology to stimulate deeper regions of the brain, including the medial prefrontal cortex, which is involved in emotion regulation and top-down behavioral control, and the anterior cingulate cortex, which contributes to several functions that are impaired in OCD (including error monitoring, conflict resolution, and integrating motivation and emotion with movement). In a pivotal early trial involving 11 sites, 99 adults with OCD who previously responded poorly to SSRIs or CBT received 6 weeks of daily treatment with either high-frequency dTMS targeting the medial prefrontal cortex and dorsal anterior cingulate cortex or sham dTMS. Critically, personalized symptom provocations (e.g., encouraging a participant with contamination fears to think about a dirty door handle) were delivered shortly before each dTMS session in order to activate the relevant brain circuitry. dTMS treatment led to a significantly greater response rate compared with sham treatment (38.1% vs. 11.0%, respectively), an effect that was sustained at 1-month follow-up (Carmi *et al.* 2019). Based on these findings, dTMS received FDA clearance for its use to treat OCD symptoms in August 2018, and remains the only neuromodulatory approach to attain such clearance. Subsequently, a multicenter study including 219 adults with OCD who were recruited from 22 community sites and were treated with the above protocol found that 58% of patients experienced a Y-BOCS score reduction of at least 30% after 29 dTMS sessions (Roth *et al.* 2021).

Across these studies, both rTMS and dTMS were generally well tolerated. Common side effects included localized scalp discomfort, muscle twitches, lightheadedness, and headaches. More serious concerns include hearing loss (although this is preventable by using earplugs) and seizures (McCathern *et al.* 2020).

Neurosurgery

Between 10% and 40% of patients with OCD will continue to have severe symptoms despite receiving evidence-based treatments (Fineberg *et al.* 2020). For individuals with intractable OCD symptoms, neurosurgery may be considered as a treatment of last resort. Ablative procedures and deep brain stimulation (DBS) are the two most researched techniques and are typically delivered in combination with medications and/or CBT.

Cingulotomy and anterior capsulotomy are ablative procedures that have been used to treat refractory OCD for more than 50 years. A systematic review of 10 studies including 193 patients concluded that both techniques were effective, leading to significant improvement in 25%-50% of patients (Pepper *et al.* 2015). Although these procedures were reasonably well tolerated, the rates of serious or permanent adverse events were high (5.2% of patients who received cingulotomy and 21.4% of those who received anterior capsulotomy).

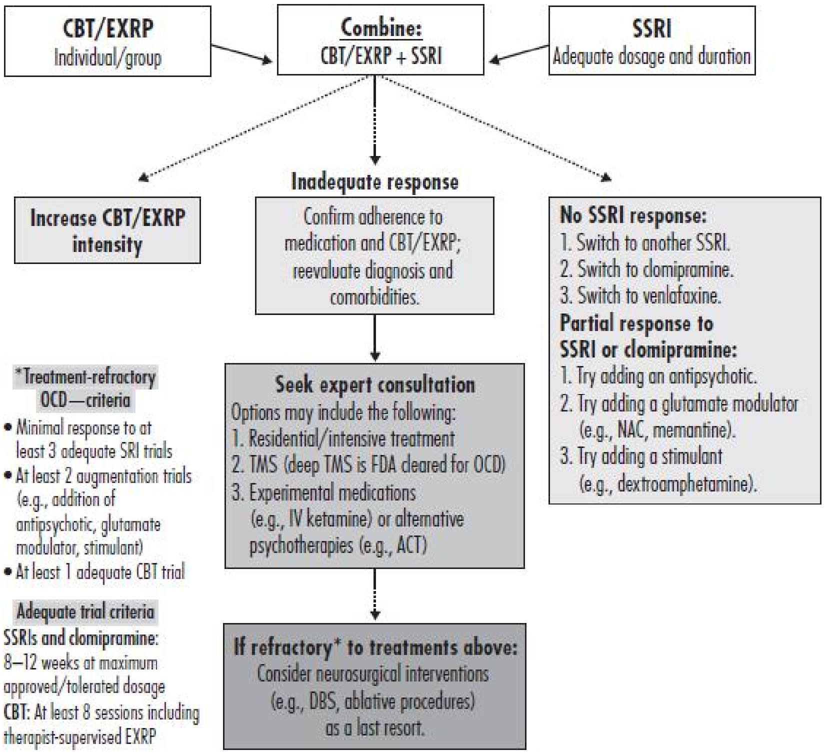
DBS has shown promise as a potentially reversible alternative to ablative procedures and, as of 2009, has received a humanitarian exemption from the FDA permitting its use to treat patients with refractory OCD (Wu *et al.* 2021). DBS for OCD typically involves implanting an electrode in the vicinity of the ventral anterior capsule and ventral striatum, which includes the nucleus accumbens and bed nucleus of the stria terminalis. Open-label studies (de Koning *et al.* 2016) and two blinded randomized controlled trials (Denys *et al.* 2010; Luyten *et al.* 2016) found substantial acute improvement among patients with treatment-refractory OCD who received DBS, with Y-BOCS scores decreasing by nearly 40%. However, the long-term effects of DBS remain unknown. Although DBS's reversibility is an advantage over ablative procedures, a recent meta-analysis found that DBS and ablative procedures had similar efficacy. Increased impulsivity was also a more common side effect with DBS than with ablative procedures (Hageman *et al.* 2021). Given the limited number of trials and small samples that have been used to date, neurosurgery is still considered an experimental treatment by most guidelines (Wu *et al.* 2021), and its use should be reserved for only the most severe cases.

Emerging Neuromodulation Techniques

The surge in neuromodulation research over the past few years has included studies of several novel techniques in patients with OCD. These approaches are summarized in Table 52-4. Transcranial electric current stimulation, which includes transcranial direct current stimulation and transcranial alternating current stimulation, involves applying a weak electric current to targeted brain regions through an anode and a cathode placed on the scalp. Transcranial direct current stimulation applied to the SMA and OFC has shown early promise for treating OCD in small controlled trials (da Silva *et al.* 2021; Gowda *et al.* 2019), although interpreting these findings is difficult given inconsistencies in the transcranial direct current stimulation protocol used. Magnetic seizure therapy, a therapeutic strategy similar to electroconvulsive therapy, involves applying magnetic stimulation to the brain to induce a generalized seizure. A small trial in 10 patients did not find magnetic seizure therapy to be effective for OCD symptoms (Tang *et al.* 2021). Ultrasound capsulotomy is a novel procedure in which focused ultrasound is used to lesion a small portion of the internal capsule. A recent case series suggests that ultrasound capsulotomy may be an alternative to ablative neurosurgery for some patients with treatment-refractory OCD (Germann *et al.* 2021). However, studies to optimize the procedures and targets involved are needed before ultrasound capsulotomy can be used outside of research settings.

Treatment Algorithms

As reviewed in this chapter, clinical research over the past decade has revealed a variety of new approaches to pharmacological treatment of OCD. Among these agents, SSRIs remain the first-line treatment (alongside EXRP), given the robust evidence supporting their safety and efficacy. However, only a minority of patients with OCD will achieve a complete response to an initial SSRI trial, even after optimizing the dosage and duration (Farris *et al.* 2013). In this situation, it is often reasonable to switch to another SSRI or to clomipramine. Options for patients whose symptoms do not respond to multiple SRI trials include switching to another serotonergic drug (e.g., venlafaxine, mirtazapine) or augmenting with another medication (e.g., an antipsychotic, a glutamate modulator, a stimulant). When symptoms persist despite these interventions, consulting with an expert in OCD treatment is advisable. Treatment options at this stage may include residential treatment, experimental medications (e.g., ketamine), or neuromodulation approaches (e.g., dTMS). Finally, in severe, treatment-refractory cases of OCD, neurosurgical approaches are available as a last resort. The above-described treatment algorithm is summarized in Figure 52-1.

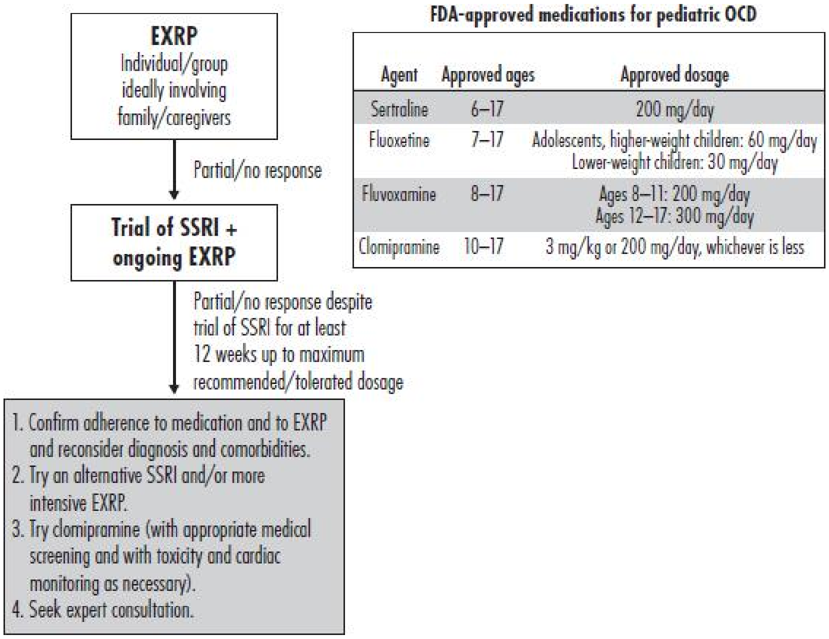


CBT/EXRP
Individual/group
Combine:
CBT/EXRP + SSRI
SSRI
Adequate dosage and duration
Inadequate response
Increase CBT/EXRP intensity
Confirm adherence to medication and CBT/EXRP; reevaluate diagnosis and comorbidities.
No SSRI response:
1. Switch to another SSRI.
2. Switch to clomipramine.
3. Switch to venlafaxine.
Partial response to SSRI or clomipramine:
1. Try adding an antipsychotic.
2. Try adding a glutamate modulator (e.g., NAC, memantine).
3. Try adding a stimulant (e.g., dextroamphetamine).
*Treatment-refractory OCD—criteria
• Minimal response to at least 3 adequate SRI trials
• At least 2 augmentation trials (e.g., addition of antipsychotic, glutamate modulator, stimulant)
• At least 1 adequate CBT trial
Adequate trial criteria
SSRIs and clomipramine: 8–12 weeks at maximum approved/tolerated dosage
CBT: At least 8 sessions including therapist-supervised EXRP
Seek expert consultation
Options may include the following:
1. Residential/intensive treatment
2. TMS (deep TMS is FDA cleared for OCD)
3. Experimental medications (e.g., IV ketamine) or alternative psychotherapies (e.g., ACT)
If refractory* to treatments above:
Consider neurosurgical interventions (e.g., DBS, ablative procedures) as a last resort.

FIGURE 52-1. Treatment algorithm for OCD in adults.

ACT = Acceptance and Commitment Therapy; CBT = cognitive-behavioral therapy; DBS = deep brain stimulation; EXRP = exposure and response/ritual prevention; NAC = *N*-acetylcysteine; SRI = serotonin reuptake inhibitor; SSRI = selective serotonin reuptake inhibitor; TMS = transcranial magnetic stimulation.

The majority of the treatment studies conducted thus far (and reviewed in this chapter) have involved adults. However, epidemiological studies suggest that the onset of OCD symptoms occurs before age 19 years in approximately 50% of patients with OCD and before age 14 years in around 25% (Ruscio *et al.* 2010). Treatment of children and adolescents with OCD presents a clinical challenge because of the limited data available and increased concern for adverse medication effects in pediatric patients, and thus requires a different approach (Figure 52-2). Given these concerns and the strong support for the safety and efficacy of CBT for children and adolescents with OCD (Pediatric OCD Treatment Study [POTS] Team 2004), most guidelines recommend CBT as the first-line treatment for this population before any medication is started (Weidle *et al.* 2021).



EXRP
Individual/group ideally involving family/caregivers
Partial/no response
Trial of SSRI + ongoing EXRP
Partial/no response despite trial of SSRI for at least 12 weeks up to maximum recommended/tolerated dosage
1. Confirm adherence to medication and to EXRP and reconsider diagnosis and comorbidities.
2. Try an alternative SSRI and/or more intensive EXRP.
3. Try clomipramine (with appropriate medical screening and with toxicity and cardiac monitoring as necessary).
4. Seek expert consultation.

FDA-approved medications for pediatric OCD

Agent	Approved ages	Approved dosage
Sertraline	6–17	200 mg/day
Fluoxetine	7–17	Adolescents, higher-weight children: 60 mg/day Lower-weight children: 30 mg/day
Fluvoxamine	8–17	Ages 8–11: 200 mg/day Ages 12–17: 300 mg/day
Clomipramine	10–17	3 mg/kg or 200 mg/day, whichever is less

FIGURE 52-2. Treatment algorithm for OCD in children and adolescents.

EXRP = exposure and response/ritual prevention; SSRI = selective serotonin reuptake inhibitor.

In children and adolescents who experience an inadequate response to an initial CBT trial, SSRIs are considered second-line treatments. In the POTS trial, SSRIs had similar efficacy compared with CBT in 112 children and adolescents with OCD who were treated for 12 weeks. Notably, the combination of CBT and SSRIs was more effective than either treatment alone, and SSRIs were associated with a higher side-effect burden (POTS Team 2004). Of the SSRIs, only fluoxetine, fluvoxamine, and sertraline are FDA approved for the treatment of pediatric OCD in the United States, although there is little theoretical basis to suggest that these agents are superior to other available SSRIs. Clomipramine is also FDA approved for treating pediatric OCD, and it can be considered as a third-line agent in patients whose symptoms do not respond to two adequate SSRI trials (Varigonda *et al.* 2016).

Other pharmacological approaches studied in pediatric patients include augmenting SRIs with the glutamate modulators NAC and memantine (Ghanizadeh *et al.* 2017; Hezel *et al.* 2009; Li *et al.* 2020). Another glutamate modulator, D-cycloserine, has also been evaluated as a potential augmenter of CBT in children and adolescents with OCD (Wilhelm *et al.* 2018). Most other agents that have been tested in adults (including antipsychotics, stimulants, TMS, and neurosurgical approaches) have not been studied in pediatric populations and thus their use cannot be recommended. In particular, the use of antipsychotics should be avoided given the lack of support for their efficacy and their association with weight gain, metabolic syndrome, and other long-term adverse effects. Given the risk for adverse effects and limited information available to guide clinical decisions, seeking expert consultation is usually recommended when considering a trial of clomipramine or an experimental medication in children and adolescents with OCD.

Conclusion

OCD was once considered a rare and essentially untreatable condition. Although it remains a serious and debilitating disorder, fortunately our understanding of the phenomenology and treatment of OCD has improved dramatically over the past 40 years. Randomized controlled trials have established the efficacy of SRIs as first-line agents in OCD treatment. For those unresponsive to initial treatment, studies have also suggested next-step strategies, including switching to other serotonergic medications and augmenting with agents from other classes (e.g., antipsychotics, glutamate modulators). Preliminary studies have begun to identify and test new treatment approaches, including medications with novel mechanisms (e.g., ketamine, anti-inflammatories), pharmacological augmentation of CBT, and neuromodulation (e.g., TMS). Neurosurgical treatment remains available as a last resort. Some of the patients who receive the evidence-based treatments reviewed earlier (see Figures 52-1 and 5-2) can be expected to achieve wellness (i.e., minimal symptoms [Farris *et al.* 2013]), whereas even more will experience at least some symptom relief.

On the other hand, the substantial minority of patients who do not benefit from currently available treatments, or who cannot tolerate them due to side effects, is a reminder that we have much to learn. In particular, randomized controlled trials of medications with novel targets (i.e., those other than the monoamine systems) and of neuromodulation are needed to better establish the role of these approaches in OCD treatment. In addition, randomized controlled trials of medications in children and adolescents with OCD are sorely needed, given the limited research in pediatric populations to date. Other areas in need of further exploration include approaches to treating OCD comorbid with other psychiatric disorders, strategies to optimize the combination of psychopharmacology and psychotherapy for OCD, and ways to make the above treatments accessible to a broader and more diverse patient population.

CHAPTER 53

Treatment of Schizophrenia

Mary F. Brunette, M.D.
Jacob S. Ballon, M.D.
Samantha A. Gnanasegaram, M.D.
Agnieszka Kalinowski, M.D., Ph.D.
William R. Keller, M.D.
Jeffrey D. Reed, D.O.
Doug L. Noordsy, M.D.

Schizophrenia is a brain disorder characterized by a chronic relapsing and remitting course of psychosis that is often accompanied by persistent "deficit" features such as cognitive dysfunction and negative symptoms. This disorder seems to be similarly prevalent across geographical and cultural boundaries (Jablensky *et al.* 1992), affecting nearly 1% of the population (Charlson *et al.* 2018; Perala *et al.* 2007).

Considerable progress has been made in the pharmacological treatment of schizophrenia since the serendipitous discovery of chlorpromazine in the 1950s. Other antipsychotics, which share chlorpromazine's dopamine type 2 (D_2) receptor-blocking activity, were subsequently developed. These first-generation, or conventional, antipsychotics are all effective in the treatment of positive symptoms of psychosis but have limited beneficial effects on negative symptoms and cognitive deficits.

Since 1990, an array of second-generation agents have been developed. These medications have been referred to as atypical or novel antipsychotics because of their lower propensity (compared with many first-generation agents) to cause extrapyramidal side effects (EPS). This may contribute to the unique profile of some second-generation antipsychotics (Seeman 2002).

Pharmacological treatment should be personalized for each individual and include targeting positive symptoms of the illness as well as negative symptoms, cognitive impairment, and comorbid conditions while addressing potential side effects and physical health. Second-generation agents result in only modest improvement in mood, negative, and cognitive symptom clusters, which has led to hypotheses involving the effects of various receptor activities (e.g., serotonin type 7 [5-HT_7]) and to the development of compounds specifically targeted at negative and cognitive symptoms (Young and Geyer 2015). There has also been a concerted effort to develop antipsychotic medications with primary actions in the glutamatergic, muscarinic, trace amine-associated receptor 1 (TAAR-1), and D-amino acid oxidase systems.

In addition, schizophrenia has been increasingly conceptualized as a neurodevelopmental disorder (Insel 2010). In this context, the field has focused on early diagnosis and intervention during the prodromal phase, before the onset of overt psychosis, to improve the overall course or even prevent the onset of illness in individuals at risk of developing schizophrenia (Mei *et al.* 2021).

This chapter addresses the diagnosis and psychopharmacological treatment of schizophrenia as well as the common comorbidities of this illness.

Clinical Manifestations of Schizophrenia

There is a general consensus, following the seminal work of several investigators (Andreasen 1985; Crow 1985), that schizophrenia can be conceptualized as a disorder with at least two dimensions of symptomatology, in addition to the presence of cognitive impairments, that may be present at very different levels among individuals.

Positive Symptoms

Positive symptoms are perceptual or cognitive features that individuals without psychiatric disorders usually do not experience. They include hallucinations, delusions, and disorganized thinking, although disorganization also can be conceptualized as an independent symptom dimension (Liddle *et al.* 1989). Positive symptoms tend to respond to treatment with antipsychotic medications. These symptoms do not predict the long-term functional outcome of the illness (Green *et al.* 2000). Psychotic symptoms are not unique to schizophrenia; they can occur in a wide spectrum of other psychiatric, neurological, and medical disorders. Therefore, it is essential to rule out other possible causes of psychosis before a diagnosis of schizophrenia is made.

Negative Symptoms

Negative symptoms represent a "loss" of functions or abilities that people without schizophrenia usually possess. They include anhedonia, affective flattening, alogia, avolition, and asociality. Negative symptoms are associated with intellectual and neurocognitive impairment and are stronger predictors of long-term functional outcome than are positive symptoms (Harvey and Keefe 1998). However, neurocognitive deficits (discussed next) remain the strongest predictors of outcome (Green 1996).

The concept of primary versus secondary negative symptoms may provide a useful framework for assessing symptoms (Carpenter *et al.* 1988). *Primary* negative symptoms represent the core negative symptoms reflecting the disease process. *Secondary* negative symptoms, on the other hand, are caused by or are secondary to positive symptoms of psychosis or the antipsychotic medications themselves. A reduction in medication dosage may alleviate some secondary negative symptoms, but this strategy is unlikely to have a beneficial effect on primary negative symptoms.

Neurocognitive Deficits

People with schizophrenia also may experience a decline in cognitive functions, including verbal declarative memory, working memory, executive function, and attention. As described later in the section titled "Course of Schizophrenia," there is strong evidence that cognitive deficits predate the onset of psychosis in many people, followed by a significant decline during the early course of the illness (Keefe 2014; Lam *et al.* 2018). After this initial decline, cognitive function remains relatively stable without significant further deterioration (Heilbronner *et al.* 2016).

Diagnosis of Schizophrenia

According to DSM-5-TR (American Psychiatric Association 2022), to make the diagnosis of schizophrenia, there must be evidence of continuous symptomatic disturbance for at least 6 months accompanied by a decline from the premorbid level of functioning. This 6-month period can include functional deterioration occurring during the prodromal phase before the onset of overt psychosis. Within the 6-month period, the patient must have experienced two or more of the following symptoms for at least 1 month: delusions, hallucinations, disorganized speech, grossly disorganized or catatonic behavior, or negative symptoms; and one of these must be a positive symptom (delusions, hallucinations, or disorganized speech). If the duration of psychotic symptoms is less than 1 month because of successful treatment with antipsychotic medication, a diagnosis of schizophrenia may still be made.

Course of Schizophrenia

Schizophrenia may be characterized as a heterogeneous neurodevelopmental disorder in which psychotic symptoms develop in adolescence or young adulthood (McCutcheon *et al.* 2020). In the 2-5 years before the onset of the first psychotic episode, up to three-quarters of patients experience a range of nonspecific prodromal symptoms, demarcating an at-risk state for the development of psychosis or other mental disorders (Yung and McGorry 1996).

Clinically, the prodromal period is often characterized by depression, anxiety, social withdrawal, sleep disturbances, and reductions in motivation, cognition, and attention (Devoe *et al.* 2019). Transition from this prodromal period to the first psychotic episode is often triggered by an acute stressor that may include substance use (Devoe *et al.* 2019; Oliver *et al.* 2020). After the initial period of psychosis, the course is often characterized by a gradual deterioration in function over the next 5 years and then symptoms and functioning tend to stabilize, although some people experience full recovery from symptoms (Van Eck *et al.* 2018). The average age at onset is approximately 5 years later in women than in men, and women tend to have more favorable outcomes.

Schizophrenia is a highly heritable disease. Genome-wide association studies have found more than 200 genetic loci of interest associated with the risk of schizophrenia that contribute to the polygenic risk score for predicting likelihood of onset in a clinical population (Perkins *et al.* 2020; Ripke *et al.* 2014; Trubetskoy *et al.* 2022). Accumulating evidence (reviewed in Howes and Onwordi [2023] and McCutcheon *et al.* [2020]) indicates that genetic vulnerability and/or environmental stress lead to disruption in early brain development, potentially through alterations of synaptic expression, increasing the risk for schizophrenia. During adolescence, abnormal pruning may be driven by high *C4A* gene expression (Sekar *et al.* 2016). Decreased synaptic density or aberrant synapse function may then contribute to cortical excitatory-inhibitory imbalance and dysregulation in subcortical dopaminergic circuitry, leading to the development of cognitive and negative symptoms and positive symptoms of psychosis, respectively.

Functional outcomes are more closely associated with the level of cognition than with the severity of positive symptoms (Green 2016; Wells *et al.* 2015). Several large-scale studies have demonstrated that individuals with schizophrenia can be separated into three groups based on the trajectory of cognition as measured by IQ: the first group demonstrates early childhood cognitive impairment manifesting with low IQ and a global pattern of neurocognitive deficits; a second group demonstrates relatively stable cognitive development through adolescence and intact cognition despite emerging psychosis and intermittent positive symptoms over time; and a third group demonstrates steep decline in cognition during the adolescent period (Dickinson *et al.* 2020; Weinberg *et al.* 2016). Brain volume and genetic risk have been shown to cluster along these three trajectories (Dickinson *et al.* 2020; Weinberg *et al.* 2016). Individuals in the preadolescent cognitive impairment and adolescent decline groups experience poorer functional outcomes with global neurocognitive impairment. Some studies have found that impairment in schizophrenia is associated with particular cognitive domains, such as processing speed, attention, executive function, nonverbal memory, and working memory (Niarchou *et al.* 2013; Taylor *et al.* 2020).

Although schizophrenia is clearly a heterogeneous condition, studies suggest a better prognosis, at least in the initial course of illness, when treatments are provided early to minimize the duration of untreated psychosis (Kane *et al.* 2015; Van Eck *et al.* 2018; Robinson *et al.* 2022). Thus, a major goal in the treatment of schizophrenia is early recognition and timely treatment.

Pharmacological Management of Schizophrenia

Acute Psychosis

The acute phase of schizophrenia is characterized by psychotic symptoms that often lead to agitation and severe distress. Affective symptoms such as depression and mania also may be present. Patients who are unable to care for themselves or who show a risk of harming themselves or others may require hospitalization to stabilize their symptoms.

Antipsychotic medications are widely used and largely effective for the treatment of acute psychosis. Treatment of a patient with acute agitation and psychosis may require parenterally administered antipsychotic medication. Many physicians still use a high-potency first-generation antipsychotic (often haloperidol) in conjunction with a benzodiazepine (e.g., lorazepam) and/or an anticholinergic drug (e.g., benztropine) for acute symptom management. Intramuscular administration of a second-generation antipsychotic, such as olanzapine or ziprasidone, is also common. When olanzapine is used intramuscularly, benzodiazepines should be avoided because of an increased mortality risk associated with the combination (Marder *et al.* 2010).

If the patient has a history of treatment with antipsychotic medications, the clinician should ascertain whether the current psychosis is the result of nonadherence to the medication regimen, treatment resistance, or loss of therapeutic response to the medications. Patients often decide to stop taking antipsychotic medications, leading to symptom exacerbation or full-blown relapse (Mi *et al.* 2020). Reasons for stopping antipsychotics vary, but the most common are unpleasant side effects, anosognosia, delusional interpretations about medical care, substance use, and lack of a supportive environment (Kampman and Lehtinen 1999; Lacro *et al.* 2002). When patients choose to stop medication, it is imperative 1) to elicit and understand the reasons for their choice, 2) to provide psychoeducation to patients and their key supporters about risks of untreated psychosis, 3) to explore strategies to increase adherence or alternative treatment options, and 4) to develop a plan for medication and other treatment use going forward, which may include daily support and monitoring. Long-acting injectable medications should be considered, although long-acting medications do not guarantee long-term adherence (Kishimoto *et al.* 2018). In the case of treatment resistance or breakthrough psychosis while the patient is taking medication regularly, a change in the patient's medication regimen may be indicated.

Causes of psychosis exacerbation may include comorbid substance use disorder as well as trauma or other psychosocial stressors such as difficulties with housing, employment, benefits, insurance, disability, family members, or friends. Therefore, although medications are an important component in the treatment of psychosis, other interventions such as psychotherapy, group therapy, family therapy, dual-diagnosis treatment, social skills training (SST), and case management are important adjuncts to pharmacological management to improve coping at every stage of illness.

First-Episode Psychosis

Emphasis on the early diagnosis and treatment of the first psychotic episode of schizophrenia arises from evidence suggesting that longer durations of untreated psychosis may be associated with poorer long-term outcomes (Albert and Weibell 2019). Unfortunately, the average time between onset of symptoms and initiation of treatment in the United States has been up to a year and a half (Addington *et al.* 2015). Coordinated specialty care provided to patients and their families as early as possible in the course of illness reduces the duration of untreated psychosis, improves outcomes, and may reduce disability (Correll *et al.* 2018; Kane *et al.* 2016).

Because of their reduced risks of neurological side effects (parkinsonism, akathisia, and tardive dyskinesia), the second-generation antipsychotics are commonly used in the initial treatment of people in their first episode of psychosis. Because patients are likely to require long-term treatment, clinicians should choose medications with the lowest risk for cardiometabolic side effects (weight gain, hyperlipidemia, and glucose intolerance), monitor side effects regularly in accordance with published guidelines (American Diabetes Association *et al.* 2004), and adjust medication types and dosages based on their efficacy and tolerability. To provide the flexibility to switch from oral to long-acting injectable agents, clinicians may encourage initial use of medications that are available in both

formulations and effective in first-episode psychosis, including paliperidone, risperidone, aripiprazole, and olanzapine (Kane *et al.* 2020).

In discussing medication options with patients and their families, clinicians can use a shared decision-making approach (Deegan and Drake 2006) to maximize tolerability and ultimately adherence. Medications should be initiated at very low dosages, as these patients often respond robustly to low doses and are sensitive to side effects (American Psychiatric Association 2021). If needed, the dosage can be slowly titrated up to produce a full response.

After remission of an initial episode of psychosis, many patients are interested in tapering off medication. However, 10 randomized controlled trials demonstrated that relapse rates were twice as high among individuals who discontinued antipsychotic medication compared with those who maintained antipsychotic use during the first 24 months of treatment, and the risk was not different based on sudden versus gradual discontinuation; however, almost half of patients in the discontinuation groups did not experience relapse (Kishi *et al.* 2019). Predictors of relapse include antipsychotic nonadherence, persistent substance use disorder, criticism from caregivers, and poorer premorbid function (Alvarez-Jimenez *et al.* 2012). A careful, personalized discussion about medication risks and benefits should guide any decision to taper medication, and tapers should be conducted very slowly, with close monitoring during and afterward to allow for rapid reinitiation of medication if needed (Horowitz *et al.* 2021).

Choice of Antipsychotics

Since the early 1990s, second-generation antipsychotics have been used widely. Two government-sponsored studies, the U.K. National Health Service Cost Utility of the Latest Antipsychotic Drugs in Schizophrenia Study (CUtLASS; Jones *et al.* 2006), and the U.S. National Institute of Mental Health-sponsored Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE; Lieberman *et al.* 2005), demonstrated similar effectiveness between first-and second-generation antipsychotics. The CATIE study was designed to compare the effectiveness of four second-generation antipsychotics (olanzapine, quetiapine, risperidone, and ziprasidone) and a representative first-generation antipsychotic (perphenazine) in "real-world" patients with schizophrenia. The primary outcome measure was treatment discontinuation. Of the 1,432 participants who received at least one dose of medication, 74% discontinued the study medication before 18 months: 64% of the subjects taking olanzapine discontinued compared with 74%-82% of those taking perphenazine, quetiapine, risperidone, or ziprasidone. More subjects receiving olanzapine discontinued because of weight gain and metabolic effects, whereas more subjects assigned to perphenazine discontinued because of EPS. For patients whose symptoms failed to improve with a newer second-generation antipsychotic, clozapine was more effective than switching to another second-generation antipsychotic (McEvoy *et al.* 2006).

Since the CATIE study was published, many new antipsychotics (e.g., asenapine, brexpiprazole, cariprazine, iloperidone, lurasidone, lumateperone, olanzapine-samidorphan, paliperidone) have been approved by the FDA. A very limited number of direct-comparison studies seem to suggest that these new antipsychotics are neither more nor less efficacious compared with older second-generation antipsychotics (Fu *et al.* 2014).

Neither the CATIE nor the CUtLASS study addressed the comparative effects of oral versus long-acting injectable antipsychotics. A meta-analysis of the many types of trials of long-acting injectable antipsychotics demonstrated a benefit for reducing relapse and rehospitalization (Kishimoto *et al.* 2021), as was demonstrated in a pragmatic

clinical trial among patients in their first episode (Kane *et al.* 2020). At present, risperidone, paliperidone, olanzapine, and aripiprazole are available in long-acting injectable formulations, and others are expected to be developed in the coming years.

Although antipsychotics can be highly effective for many people, they are not without their shortcomings. Patients need to be well informed about the different tolerability profiles among antipsychotic medications. As is discussed in more detail later in this chapter (see "Management of the Side Effects of Antipsychotic Medications"), several of the first-generation agents carry a high risk of EPS and tardive dyskinesia (Glazer 2000). Risperidone and paliperidone may elevate serum prolactin levels and may cause EPS at higher dosages. Iloperidone may elevate serum prolactin to a lesser degree. Akathisia and other EPS may be common with aripiprazole, brexpiprazole, cariprazine, and lurasidone. Weight gain and metabolic disturbances are associated with many antipsychotic medications, with olanzapine and clozapine having the highest likelihood and lurasidone the lowest likelihood of these effects (Bernardo *et al.* 2021). Sedation is most common in patients receiving asenapine, quetiapine, olanzapine, ziprasidone, or clozapine. Ziprasidone, paliperidone, and iloperidone may cause QTc interval prolongation and should be used with caution in patients at risk for this effect. Finally, because of its risks for agranulocytosis, seizures, and myocarditis, clozapine is generally reserved for patients with treatment-resistant illness or suicidality. However, experts recently recommended a tailored titration approach based on personal ancestry and monitoring to improve the safety of using this medication (de Leon *et al.* 2022). Table 53-1 lists the available formulations for the commonly used first-generation antipsychotic medications and all of the second-generation agents.

TABLE 53-1. Antipsychotic medications

Antipsychotic name	**Tablet/capsule**	**Orally disintegrating tablet**	**Liquid**	**Short-acting injection**	**Long-acting injection**	**Other**
Commonly used first-generation agents						
Chlorpromazine (low potency)	X		X	X		
Perphenazine (midpotency)	X					
Perphenazine-amitriptyline	X					
Loxapine (midpotency)	X					X[a]

[a] Loxapine inhalation powder.

[b] Asenapine transdermal patch.

[c] Risperidone long-acting injection includes intramuscular and subcutaneous formulations.

Antipsychotic name	**Tablet/capsule**	**Orally disintegrating tablet**	**Liquid**	**Short-acting injection**	**Long-acting injection**	**Other**
Fluphenazine (high potency)	X		X	X	X	
Haloperidol (high potency)	X		X	X	X	
Second-generation agents						
Aripiprazole	X	X	X		X	
Asenapine		X				X[b]
Brexpiprazole	X					
Cariprazine	X					
Clozapine	X	X	X			
Iloperidone	X					
Lumateperone	X					
Lurasidone	X					
Olanzapine	X	X		X	X	
Olanzapine-fluoxetine	X					
Olanzapine-samidorphan	X					
Paliperidone	X				X	
Quetiapine	X					
Risperidone	X	X	X		X[c]	
Ziprasidone	X			X		

[a] Loxapine inhalation powder.

[b] Asenapine transdermal patch.

[c] Risperidone long-acting injection includes intramuscular and subcutaneous formulations.

Maintenance Treatment

The major goals of maintenance treatment are to prevent relapse and to improve psychosocial and vocational functioning. Tailored psychopharmacological and psychosocial treatments should be combined to treat psychosis and improve functioning. The treatment and prevention of other psychiatric comorbidities is an important aspect of maintenance treatment. In addition, the prevention and treatment of medical comorbidities has become a very important part of long-term management.

Prevention of relapse improves long-term clinical outcomes. With each relapse, the time required to regain clinical stability typically lengthens, with the possible consequence of greater treatment resistance. Because nonadherence to medication is a significant predictor of relapse, clinicians must work with patients to develop a medication regimen that is acceptable to the patient. Ongoing use of shared decision-making (Deegan and Drake 2006) to find a medication regimen that is acceptable to the patient is key; this process can enhance communication, develop collaboration in working toward mutually agreed-upon goals, and identify areas of agreement that can lead to better overall medication tolerance and adherence and illness recovery (Hamann *et al.* 2020). Recently, experts recommended simplifying medication taking by using a single daily oral dose or a monthly or quarterly injection as well as improving tolerability by using lower doses (Takeuchi *et al.* 2021).

Treatment of Persistent Psychotic Symptoms

At least 30% of patients will have persistent psychotic symptoms despite consistent use of antipsychotics (Wagner *et al.* 2020). This treatment-refractory or treatment-resistant

psychosis is defined by 1) the lack of significant response to at least three adequate trials of antipsychotics from at least two different chemical classes in the past 5 years and 2) persistently poor social and occupational functioning.

Available data indicate that clozapine is the most effective drug for treatment-resistant schizophrenia (Siskind *et al.* 2016). Practice guidelines consistently recommend a trial of clozapine for patients who experience persistent psychotic symptoms. However, because of the serious side effects that may be associated with clozapine and the requirement for frequent white blood cell count monitoring in many countries, some patients and psychiatrists are reluctant to use this agent; thus, many patients with treatment-refractory psychosis never receive a trial. Among those who do, approximately a third experience persisting symptoms.

Multiple controlled trials have assessed whether combining two antipsychotics is more effective than antipsychotic monotherapy. Although augmentation with aripiprazole, fluoxetine, or valproate may provide benefit for individuals who experience minimal treatment response to clozapine (Siskind *et al.* 2018), the overall evidence for combining two antipsychotics is mixed and inconclusive. Many patients taking two antipsychotics can safely switch back to a single agent (Essock *et al.* 2011). Given the heterogeneity of treatment-refractory presentations, more research is needed to guide personalized treatment for patients with severe and resistant symptoms.

Treatment of Cognitive Deficits

Neurocognitive deficits, especially disturbances in executive functioning, memory, and attention (Green *et al.* 2000), are closely associated with the long-term functional outcome of patients with schizophrenia. Second-generation antipsychotics may improve some aspects of cognition in schizophrenia more effectively compared with haloperidol, as found in meta-analysis reports (e.g., Desamericq *et al.* 2014). The therapeutic effects of the newer antipsychotics are most notable in measures of verbal fluency and executive functioning, whereas improvement in memory may be more limited. However, data from the CATIE trial showed that at 18 months of treatment, perphenazine was more effective than any of the second-generation antipsychotics in improving all domains of neurocognitive deficits (Keefe *et al.* 2007). It is not clear, however, whether statistically significant improvements in neurocognition measured in the laboratory translate into improved functional outcomes in terms of employment, school performance, or social roles, for example (Green 2002). When added to standard treatment, cognitive remediation--a training approach designed to improve cognitive skills and function--improves cognition with small to medium effect sizes (Lejeune *et al.* 2021). Exercise also has been shown in 10 trials to improve cognition (Firth *et al.* 2017).

Behavioral and Psychosocial Management of Schizophrenia

Despite the proven efficacy of antipsychotics in the treatment of schizophrenia, most patients continue to experience some degree of residual positive symptoms, negative symptoms, and cognitive deficits, and many have difficulty attaining or regaining their desired level of social and occupational functioning. To date, several different

types of psychosocial interventions have been empirically shown to improve function and/or reduce rates of relapse and rehospitalization, and a variety of treatments may assist patients in acquiring social and vocational skills and possibly in managing residual psychotic symptoms (Mueser *et al.* 2013). We review key interventions next.

To address functional goals, treatment is optimally delivered by a multidisciplinary team that includes a medical professional who can prescribe medication, a psychotherapist, and clinicians skilled in psychosocial rehabilitation, including employment and housing specialists. Programs that use clinical case managers to directly assist patients in accessing services and to provide the psychosocial interventions in a community environment where skills can be practiced are ideal (Rapp and Goscha 2004). Specialized programs for people in first-episode psychosis are tailored to young people and their families to maximize engagement, rapid stabilization, and return to psychosocial functioning (e.g., Mueser *et al.* 2015).

A growing number of studies have shown that psychosocial treatments can be effective when delivered via technology (e.g., Baumel *et al.* 2016; Ben-Zeev *et al.* 2018; Brunette *et al.* 2016; Garety *et al.* 2021; Gottlieb *et al.* 2013; Rotondi *et al.* 2010), potentially increasing their reach while maintaining quality and lowering the cost of psychosocial treatment. Of importance, the interaction between pharmacological and psychosocial treatments seems to be more than additive, as each can enhance the effects of the other and affect complementary domains of outcome (Marder 2000).

Psychotherapy for Psychosis

More than 60 randomized controlled trials have demonstrated that cognitive-behavioral therapy (CBT) for psychosis is an effective addition to antipsychotic medication for the treatment of positive and negative symptoms of psychosis at both early and later stages of illness (Hardy *et al.* 2019; McDonagh *et al.* 2022), for psychosis that has not responded to medication treatment (Burns *et al.* 2014), and for people who have a high risk for but have not developed psychosis (Zheng *et al.* 2022). CBT for psychosis includes an in-depth assessment of the individual's experience of psychosis, training in coping skills, development of a shared formulation, identification and tracking of automatic thoughts, cognitive restructuring, and relapse prevention (Rathod *et al.* 2008).

Other models of psychotherapy for people with psychosis include individual resiliency training, an adaptation of CBT for psychosis for broader use (Mueser *et al.* 2015). Family therapy and multifamily groups have also demonstrated efficacy in reducing relapse risk (McDonagh *et al.* 2022).

Family and Team-Based Illness Management

It has long been noted that patients with highly critical or overinvolved family members (so-called high-expressed-emotion families) have a higher risk of relapse (Brown and Rutter 1966). Multiple studies have established the efficacy of family psychoeducational interventions (involving education and training in communication, problem-solving techniques, and/or cognitive and behavioral management strategies) in preventing relapse and improving other outcomes (McDonagh *et al.* 2022). The positive effect of family interventions persists beyond the time of the intervention (Sellwood *et al.* 2001) and is independent of both the specific form and the intensity of the intervention (Bustillo *et al.* 2001).

Assertive community treatment (ACT) has also demonstrated effectiveness in preventing relapse or rehospitalization for individuals with schizophrenia. ACT provides intensive multidisciplinary team management and service delivery in community settings for individuals who experience significant symptoms and high levels of functional impairment. At least 30 studies of ACT have shown advantages over standard treatment in reducing symptoms, family burden, and hospitalization rates and in improving independent living, housing stability, and quality of life (McDonagh *et al.* 2022; Phillips *et al.* 2001). However, it seems that the advantages of ACT do not persist after discontinuation of the program, even after prolonged delivery of services.

Interventions for Social and Vocational Functioning

SST is a strategy to help individuals acquire interpersonal disease management and independent living skills. A recent meta-analysis of 27 studies with comparators demonstrated that SST is an efficacious intervention for negative symptoms, general psychopathology, and social outcome measures when added to standard treatment including antipsychotic medication (Turner *et al.* 2018). Reviews of SST (Bellack and Mueser 1993; Kopelowicz *et al.* 2006) have described three models: basic, social problem-solving, and cognitive remediation.

Within the *basic model* of SST, complex social scenarios are broken down to simpler components, the therapist models behaviors, and the patient learns through repeated role-play. The *social problem-solving model* focuses on impaired information processing, which is thought to cause social skills deficits. This model targets symptom and medication management, recreation, basic conversation, and self-care in educational modules and is shown to be modestly effective in enhancing skills. Interventions that use cueing and support in everyday community interactions by friends or family members improve transfer of newly learned social skills to community functioning (e.g., Glynn *et al.* 2002). Finally, the *cognitive remediation model* of SST targets deficits in areas such as attention, memory, and planning, with the aim of supporting more complex cognitive processes used in learning social and other skills. An integrated approach to the concomitant training of neurocognitive and social cognitive abilities as well as social skills results in long-term improvement in social adjustment. One recent trial reported greater cognitive and functional gains when cognitive remediation was combined with physical exercise (Malchow *et al.* 2015).

Illness Management and Recovery (IMR) is a manualized package of empirically supported approaches (psychoeducation, cognitive-behavioral approaches for medication adherence, relapse prevention planning, SST, and coping skills training) delivered in weekly group or individual sessions that are used with a recovery focus that targets each individual's personal life goals (Mueser *et al.* 2006). This combination of approaches results in improved symptoms, better community functioning, and reduced hospital readmission (Bartholomew and Zechner 2014).

Although family psychoeducation, CBT, SST, and IMR may improve symptoms and social functioning, they do not seem to affect employment status. Supported employment programs have demonstrated efficacy in achieving substantial employment rates (Carmona *et al.* 2017) through rapid job searches, on-the-job training, continuous job support, and integration with mental health treatment, and they are more effective than traditional methods in helping patients obtain competitive employment. For young

people early in the course of their illness, this effective approach has been expanded to include return to education as well as employment (Ellison *et al.* 2015).

Independent housing is an important marker of community functioning. Simple provision of access to affordable housing by Section 8 certificates improves housing stability (Hurlburt *et al.* 1996). Supported housing, broadly defined as access to independent housing of the patient's choice (often supported with housing subsidies) coupled with access to community mental health and support services, improves residential stability and reduces hospitalization (Rog 2004). ACT for homeless individuals also has been shown to reduce homelessness (Coldwell and Bender 2007).

Patients and their families need information about psychosocial treatment options and should be engaged in discussions with their treatment providers about how these treatments can be useful in the context of an individual's symptoms, comorbidities, needs, and preferences.

Management of the Side Effects of Antipsychotic Medications

Pharmacological treatment of individuals with schizophrenia includes careful monitoring and management of the side effects of antipsychotics and other medications (Stroup and Gray 2018). Many patients may not spontaneously report side effects, particularly those that may be personal or embarrassing; therefore, treating clinicians can incorporate routine, systematic side-effect monitoring according to consensus guidelines into regular treatment visits (Table 53-2) (American Psychiatric Association 2021).

TABLE 53-2. Schedule for monitoring antipsychotic medication side effects

	Baseline	4 Months	Quarterly	Yearly
Metabolic				
Serum electrolytes, renal function tests, complete blood count with differential, and liver function tests	X			
Weight and height for BMI[a]	X		X	
Fasting serum lipid panel and glucose or hemoglobin A1C[b]	X	X		X

	Baseline	4 Months	Quarterly	Yearly
Hyperprolactinemia symptoms and serum prolactin[c]	X			X
Neurological				
Examination for extrapyramidal side effects, including tardive dyskinesia[d]	X			X
Cardiovascular				
Electrocardiogram to assess for QTc > 450 ms[e]	X			
Blood pressure, heart rate[f]	X			

[a] Calculated as weight in kilograms divided by height in meters squared. Take before medication initiation and monthly for first 6 months after medication initiation, then quarterly thereafter.

[b] Take before medication initiation, at 3-4 months after medication initiation, and then at least yearly thereafter.

[c] Symptoms of hyperprolactinemia should be assessed at each visit until dosing is stable, and then yearly; check serum prolactin when symptoms are present.

[d] Assess at every visit. Assess and document with assessment tools (e.g., Abnormal Involuntary Movement Scale) at least yearly, and every 6 months for high-risk patients (women, individuals older than 55 years, and those with neurological injury, past extrapyramidal side effects, and use of high dopamine$_2$-blocking antipsychotics).

[e] To assess for QTc interval prolongation before and after initiation and dosage increase in high-risk patients and with the use of chlorpromazine, droperidol, iloperidone, pimozide, sertindole, thioridazine, or ziprasidone.

[f] Taken at the initial visit and then as medically indicated.

Adverse Metabolic Side Effects and Obesity

Medication side effects, as well as lifestyle and intrinsic factors associated with schizophrenia, place patients with this disorder at increased risk for weight gain and the development of dyslipidemia, glucose intolerance, type 2 diabetes, and diabetic ketoacidosis (Freyberg *et al.* 2017). This metabolic dysregulation contributes to the development of cardiovascular diseases and the shortened life span associated with schizophrenia (Correll *et al.* 2017).

A substantial proportion of patients receiving an antipsychotic medication experience clinically significant weight gain, although weight gain propensity varies among antipsychotic medications (Pillinger *et al.* 2020). For example, the CATIE investigators found a greater than 7% weight gain from baseline in 30% of individuals receiving olanzapine, 14% of those receiving risperidone, and 7% of those receiving ziprasidone (Lieberman *et al.* 2005). This weight gain is often located in the abdomen, the region most implicated in insulin resistance (Sarsenbayeva *et al.* 2019). Weight gain and other cardiometabolic side effects may be substantially greater in young people using an antipsychotic for the first time (Tek *et al.* 2016), and obesity is already associated with hypertension in these young people (Brunette *et al.* 2023).

Insulin resistance and diabetes occur two to four times more frequently in patients with schizophrenia compared with the general population (Dixon *et al.* 2000) and may occur during antipsychotic treatment in the absence of weight gain (Ballon *et al.* 2014). The risk of diabetes is likely multifactorial, but evidence clearly indicates that antipsychotics are associated with glucose dysregulation (Jin *et al.* 2004), with clozapine and olanzapine associated with the greatest risk (Pillinger *et al.* 2020). Two genes associated with schizophrenia, Akt serine/threonine kinase (*AKT1*) and neuregulin 1 (*NRG1*), may play a role in systemic metabolic regulation (Freyberg *et al.* 2017).

Hyperlipidemia is also associated with the use of many second-generation antipsychotics (particularly clozapine, olanzapine, and quetiapine) as well as low-potency first-generation medications (Buhagiar and Jabbar 2019). The co-occurrence of atherogenic dyslipidemia with abdominal adiposity, insulin resistance, impaired fasting glucose or overt diabetes mellitus, and hypertension--known as metabolic syndrome--is associated with a significantly elevated risk for cardiovascular disease. More than 40% of CATIE participants demonstrated metabolic syndrome at baseline, with women carrying greater risk than men (McEvoy *et al.* 2005). Metabolic syndrome is associated with lower levels of aerobic fitness and greater functional impairment (Vancampfort *et al.* 2015).

The metabolic status of patients with schizophrenia should be monitored before and after treatment initiation (American Diabetes Association *et al.* 2004). Lipids, fasting glucose, and/or hemoglobin A1C should be checked at baseline, after 4 months of treatment, and annually thereafter or more frequently if dysregulation is detected. Weight to calculate BMI and blood pressure should also be checked frequently. Patients should be coached on diet and exercise strategies for metabolic health, with iterative goal-setting, progress monitoring, and discussion of impact on mental and physical health (Noordsy and Yudofsky 2019). Mental health providers should ensure that patients access primary care and should coordinate with primary care providers, particularly when metabolic symptoms become more concerning. When cardiometabolic side effects are detected, treatment providers should rapidly address the problems by switching medications or providing other behavioral or pharmacology strategies. Cardiometabolic health and side-effect risks should be a part of shared decision-making for antipsychotic treatment with patients because, for many, weight gain leads to medication discontinuation or underuse; thus, management of weight and cardiometabolic side effects has strong implications for overall adherence and clinical outcome (Vancampfort *et al.* 2019).

To avoid adverse metabolic side effects and obesity, prescribers should initiate treatment with or switch patients to antipsychotics that carry a lower risk for cardiometabolic side effects, such as a partial dopamine agonist (aripiprazole, brexpiprazole, or cariprazine) or another lower-risk second-generation antipsychotic (e.g., lurasidone, lumateperone, ziprasidone). If a patient's symptoms do not respond optimally, progression to a higher-risk antipsychotic with strong efficacy data (olanzapine or clozapine) may prove necessary. Olanzapine-samidorphan includes an opiate antagonist with potent m opioid receptor inhibition (Chaudhary *et al.* 2019) that reduces weight gain associated with olanzapine (Martin *et al.* 2019). There is no evidence yet of benefit for other metabolic parameters (Correll *et al.* 2020). Other drug targets under development for mitigating the metabolic side effects of antipsychotics include glucagon-like peptide 1 agonists, TAAR-1 agonists, and glucocorticoid/mineralocorticoid receptor antagonists.

Several other medications can be considered for off-label use to manage antipsychotic-induced metabolic dysfunction. Metformin prevents weight gain at the initiation of antipsychotic therapy and also induces modest weight loss relative to placebo (3 kg with metformin vs 1 kg with placebo) during continuation therapy (Jarskog *et al.* 2013). Moreover, metformin in combination with lifestyle changes has been found to be effective in decreasing other cardiometabolic risks (Zheng *et al.* 2019). Topiramate has also shown promise as a weight-reducing agent, although cognitive side effects may limit its utility, and it is unclear whether it is effective when used with clozapine (Correll *et al.* 2016). Glucagon-like peptide 1 receptor agonists (e.g., semaglutide) are increasingly used for weight loss (Siskind *et al.* 2019). In extreme cases, bariatric surgery may also be considered and has shown good effects on weight loss. Centrally acting sympathomimetic weight-loss drugs have the potential to increase the activity of biogenic amines and may exacerbate symptoms of psychosis in this population (Jo *et al.* 2019); thus, they should be used with extreme caution.

Neurological Side Effects

Dystonia, parkinsonism, and akathisia--known as EPS--are common neurological adverse conditions caused by antipsychotic medications. EPS are thought to arise from extensive antagonism of dopamine receptors in the striatum (Howes and Kapur 2009). Medications that block postsynaptic dopamine activity result in increased muscarinic cholinergic activity in this circuit, precipitating EPS progression (Snyder *et al.* 1974). Risk varies by antipsychotic, with the highest risk associated with antipsychotics that provide potent D_2 receptor blockade (Leucht *et al.* 2013; Shirzadi and Ghaemi 2006).

Dystonia involves spontaneous, uncontrollable muscle contractions that can be painful and distressing. These contractions may present as cervical dystonias (retrocollis and torticollis), blepharospasm, trismus, tongue protrusion, oculogyric crisis, and laryngospasm. Severe laryngospasm, with dysphagia, aspiration, and choking, can be life-threatening and thus requires immediate treatment (Kulkarni *et al.* 2017). Dystonia occurs most commonly in young male individuals shortly after the initiation of a new antipsychotic medication or following an abrupt or rapid dosage increase, with most cases occurring within 5 days of starting a medication. Approximately 5% of patients treated with intramuscular haloperidol for agitation experience dystonia within 24 hours, compared with fewer than 1% of those treated with a second-generation antipsychotic (Satterthwaite *et al.* 2008).

Antipsychotic-induced parkinsonism includes symptoms of muscle rigidity, resting tremor, bradykinesia, and affective flattening (i.e., masked faces) that occur gradually over days to months and that are more common among women and older individuals (Thanvi and Treadwell 2009). Parkinsonism is thought to result from D_2 receptor antagonism in the nigrostriatal dopamine circuit. Medication-induced parkinsonism can also precipitate anhedonia and apathy, which may be differentiated from depression and negative symptoms of schizophrenia by the presence of motor symptoms. Rabbit syndrome is a variant of parkinsonism that is characterized by a perioral and jaw tremor (Casey 1999).

Akathisia is an acute feeling of uncontrollable restlessness or an inability to remain seated or sit still. The mechanism of antipsychotic-induced akathisia is not well understood but is thought to arise from abnormal activity of the striatum affecting the adrenergic system. Medications that have lower D_2 receptor-blocking activity, partial D_2 agonist activity, or greater anticholinergic properties may be less likely to cause akathisia and are better tolerated by those who develop this side effect (Leucht *et al.* 2013; Satterthwaite *et al.* 2008).

Clinicians should regularly monitor patients for EPS using structured ratings before and after medication initiation and dosage increases (Barnes *et al.* 2020; Stroup and Gray 2018). Treatments that address EPS reduce the muscarinic cholinergic activation resulting from dopamine blockade or facilitate dopamine release. Providers can treat dystonias with anticholinergic or antihistaminergic medications such as benztropine, trihexyphenidyl, or diphenhydramine. Intramuscular anticholinergics should be used to treat acute and severe dystonias that require rapid resolution. Preventive treatment may be used for high-risk patients who require a medication with potent D_2 blockade (Satterthwaite *et al.* 2008). Dosage reduction of the antipsychotic medication should be considered first for the treatment of parkinsonism and akathisia, although resolution of these side effects may take months. Akathisia may be addressed acutely through antagonism of b-adrenergic receptors (propranolol, clonidine) or the serotonin type 2A receptor (mirtazapine) (Poyurovsky *et al.* 2006); anticholinergic and benzodiazepine agents offer limited benefit. Although benzodiazepines may reduce akathisia, their habit-forming potential should limit their use.

Tardive Dyskinesia and Tardive Dystonia

Tardive dyskinesia, a syndrome of potentially irreversible involuntary choreiform movements, and tardive dystonia, characterized by sustained muscle contractions, can gradually emerge after months of treatment with antipsychotic medications that block dopamine receptors. Because the risk of tardive dyskinesia is cumulative, it may emerge after years of treatment. These side effects typically persist beyond 1 month after medication discontinuation and can be disfiguring and debilitating (Savitt and Jankovic 2018). First-generation antipsychotic medications carry a higher long-term risk for tardive syndromes compared with second-generation medications, with rates of 32% and 13% (Correll and Schenk 2008), or 6.5% versus 2.6% per year (Carbon *et al.* 2018), respectively. Among the second-generation antipsychotics, risperidone and paliperidone confer the highest risk. Tardive dyskinesia is most common among older women, whereas tardive dystonia is more common in younger men (Solmi *et al.* 2018a). The risk for tardive dyskinesia is a robust reason for choosing second-over first-generation agents.

Tardive dyskinesia involves abnormal movements of the orofacial and buccolingual musculature manifesting as grimacing, lip smacking, chewing, and rhythmic movements of the tongue. Involvement of the neck, axial, and extremity musculature may also occur in the form of choreoathetoid movements, which may involve the laryngopharyngeal and respiratory muscles. Tardive dystonia may appear earlier in treatment than tardive dyskinesia and is characterized by slow, sustained twisting movements of the head, neck, trunk, and extremities, as well as blepharospasm, torticollis, back arching, and hyperextension of the limbs. Withdrawal tardive dyskinesia is a form of the disorder that may occur upon dosage reduction or discontinuation of an antipsychotic.

Patients who are taking antipsychotic medications should be regularly screened for tardive dyskinesia and tardive dystonia with structured rating instruments. These side effects can be addressed by reducing the dosage of the antipsychotic medication or switching from first-to second-generation agents with the lowest risk for this side effect (e.g., clozapine, olanzapine, or quetiapine) (Margolius and Fernandez 2019). Anticholinergic medications should be discontinued, as they can worsen these symptoms. For individuals with moderate to severe tardive dyskinesia, vesicular monoamine transporter 2 (VMAT2) inhibitors (e.g., deutetrabenazine, valbenazine) may be used (Solmi *et al.* 2018b). Deep brain stimulation can be considered for severe, refractory tardive syndromes. Botulinum toxin injections may be used for localized severe, refractory tardive dystonia.

Neuroleptic Malignant Syndrome

Neuroleptic malignant syndrome (NMS) is a life-threatening condition that can arise from the use of antipsychotics. The incidence of NMS was previously as high as 3%; however, more conservative prescribing practices and monitoring have likely reduced the incidence to as low as 0.01%-0.02% (Strawn *et al.* 2007). Using a nationally representative Finnish database (1972-2017), researchers reported that the rate of NMS was 0.0002% per person-year, with a death rate of 4.7% in the first month after diagnosis (Guinart *et al.* 2021). Risk factors include rapidly escalated and high dosages of antipsychotics; concomitant use of anticholinergics, lithium, and benzodiazepines; and

cardiovascular disease, catatonia, dehydration, and use of restraints (Berardi *et al.* 2002; Guinart *et al.* 2021). Symptoms of NMS include hyperpyrexia, altered consciousness, muscle rigidity, dystonia, and autonomic nervous system dysfunction. Laboratory studies may show elevated creatine phosphokinase, liver enzyme, and lactic acid levels and white blood cell counts (Strawn *et al.* 2007). Immediate treatment is crucial and includes discontinuation of antipsychotics, support of vital functions, intravenous access and fluid replenishment, and use of dopamine-potentiating agents (e.g., amantadine and bromocriptine) or muscle relaxants (e.g., dantrolene) (Pileggi and Cook 2016; Strawn *et al.* 2007). In treatment-refractory NMS, electroconvulsive therapy can be administered (Trollor and Sachdev 1999). Patients should remain off antipsychotic medications for 2 weeks after resolution of NMS before reinitiating antipsychotic treatment, which should begin with a trial of a low-dosage, low-potency antipsychotic (e.g., quetiapine or clozapine).

Hyperprolactinemia

D_2 receptor antagonism caused by first-and second-generation antipsychotics is thought to enhance the release of prolactin from the pituitary gland, leading to the signs and symptoms of antipsychotic-induced hyperprolactinemia. Medications with potent D_2 receptor-blocking effects, including most first-generation antipsychotics and some of the second-generation agents (e.g., risperidone, paliperidone, sertindole, and lurasidone) are associated with hyperprolactinemia, whereas medications with lower affinity for D_2 receptors or those that act as partial D_2 agonists (e.g., aripiprazole, brexpiprazole, cariprazine, quetiapine, and asenapine) are least likely to cause prolactinoma (Leucht *et al.* 2013). Chronically elevated serum prolactin levels can result in galactorrhea, gynecomastia, and sexual dysfunction in men as well as galactorrhea and abnormal menses in women (Haddad and Wieck 2004). Elevated serum prolactin has been associated with lower bone density in longitudinal studies (e.g., Wang *et al.* 2014), but not all studies show an association between prolactin and bone density (Lally *et al.* 2019).

Clinicians should ask patients about symptoms of hyperprolactinemia, including sexual side effects, which are concerning to patients and can lead to medication nonadherence. Serum prolactin levels should be obtained before initiating an antipsychotic, 3 months after treatment initiation, and annually thereafter (Grigg *et al.* 2017). Patients who develop hyperprolactinemia may benefit from switching to a medication with a lower propensity to cause this side effect.

Corrected QT Interval Prolongation

Several antipsychotic medications (e.g., chlorpromazine, droperidol, iloperidone, pimozide, sertindole, thioridazine, and ziprasidone) can delay cardiac ventricular repolarization, which increases the risk for torsades de pointes, an arrhythmia that can cause sudden cardiac death (Li and Ramos 2017). For individuals with cardiovascular risk factors, clinicians can assess their clinical history of palpitations, syncope, and dizziness as well as ordering an electrocardiogram to monitor for heart rate-corrected QT intervals before and after initiation of these medications. Other risk factors can be described as nonmodifiable (e.g., congenital long QT syndrome, age, sex, family history of sudden cardiac death, personal or family history of structural or functional heart disease, personal history of drug-induced QT prolongation, or metabolizer status)

and modifiable (e.g., starvation, bradycardia, excess dose or rapid intravenous infusion of QTc interval-prolonging drugs, simultaneous use of multiple drugs that prolong QTc intervals, or the risk or presence of hypokalemia, hypomagnesemia, or hypocalcemia or factors affecting drug metabolism such as drug-drug interactions, acute or chronic kidney disease, or hepatic impairment). If the QTc is greater than 450 ms or other risk factors are present, antipsychotic medications that do not cause this adverse effect should be used.

Management of Common Comorbidities in Schizophrenia

Tobacco Use Disorder

The rate of smoking among people with schizophrenia continues to be three times that seen in the general population (McClave *et al.* 2010). Cigarette smoking causes cardiovascular disease, diabetes, lung disease, and cancer and is partially responsible for excess disease burden and early mortality in schizophrenia (Callaghan *et al.* 2014). In contrast with the self-medication hypothesis, smoking abstinence does not worsen cognition or symptoms (Boggs *et al.* 2018; Evins *et al.* 2005), and quitting decreases the 10-year risk of morbidity and mortality without worsening psychosis (Thorndike *et al.* 2016).

Smoking can also complicate the treatment of schizophrenia. The hydrocarbons in smoke induce cytochrome P450 1A2 enzymes, lowering blood concentrations of clozapine and olanzapine (Tsuda *et al.* 2014). Smoke-free inpatient treatment settings reduce harm from secondhand smoke and provide a safe experience of being smoke-free (Robson *et al.* 2017). Clinicians may need to adjust antipsychotic dosages and provide nicotine replacement therapy (NRT) to treat withdrawal symptoms as patients transition in and out of smoke-free hospital settings or upon smoking cessation.

Effective intervention for cessation requires a multimodal approach that integrates motivation-based treatment (Brunette *et al.* 2020; Steinberg *et al.* 2016), behavioral addiction treatment strategies, and pharmacological treatment to address withdrawal and craving (Evins *et al.* 2019), ideally integrated into mental health treatment and provided when the patient is psychiatrically stable. Use of pharmacotherapy is safe and doubles or triples success rates (Evins *et al.* 2019). As in the general population, varenicline seems to be the most effective, followed by bupropion plus NRT, dual NRT (daily patch plus gum or lozenges as needed up to 20 times daily), or, with lower rates of effectiveness, bupropion or NRT monotherapy. Although relapse is a consideration for all smokers, those with schizophrenia experience relapse faster with discontinuation of pharmacotherapy; hence, maintenance pharmacotherapeutic and behavioral treatment for a year is important for this population (Evins *et al.* 2014). With treatment, patients with schizophrenia are able to quit smoking and thereby improve their long-term health without adverse effects on the psychotic illness.

Substance-Related Disorders

Nearly one-half of patients with schizophrenia have a lifetime history of an alcohol or drug (substance) use disorder, compared with 16% of the general population (Hunt *et al.* 2018; Regier *et al.* 1990). As in the general population, men with schizophrenia are more likely to abuse substances than are women, and the most commonly abused substances include alcohol, cannabis, opioids, and stimulants.

Without treatment, comorbid substance use disorders have a deleterious effect on the course of schizophrenia, including earlier onset of illness, worse symptoms, relapses, and hospitalizations (Grech *et al.* 1999; Schoeler *et al.* 2016) as well as early mortality (Heiberg *et al.* 2018). Among people who have not yet developed schizophrenia, psychotic syndromes triggered by substance use typically resolve within days or weeks after intoxication has resolved; however, in about a third of individuals, these syndromes may persist and develop into schizophrenia, most often with cannabis, hallucinogen, and amphetamine use (Murrie *et al.* 2020). There has been great interest in cannabis, the most frequently used illicit substance in schizophrenia (Murray *et al.* 2017). Its main psychoactive component, D-9-tetrahydrocannabinol, causes psychosis in a dose-dependent manner among patients without a cannabis use disorder, whereas cannabidiol does not (Ahmed *et al.* 2021). In some studies, approximately half of patients with first-episode psychosis already have a substance use disorder (Brunette *et al.* 2018), which complicates the diagnosis of the psychotic disorder.

Although obtaining information from patients about their use of substances should be a standard part of the medical history, problematic alcohol or substance use is often underrecognized and hence undertreated in psychiatric settings (Drake *et al.* 1993). Use of brief screening tools for substance use (e.g., Searles *et al.* 1990) can increase detection. In addition, patients often deny use; hence, clinicians should pursue collateral reports from family members, case managers, and others involved in the patient's care. Patients with schizophrenia and a comorbid substance use disorder require treatment for both disorders, optimally in programs that provide long-term comprehensive services along with integrated mental health and substance abuse treatment (Ziedonis *et al.* 2005), including motivational and cognitive-behavioral interventions, contingency management (Destoop *et al.* 2021), and medication management (Bennett *et al.* 2017).

Antipsychotic treatment should be utilized to stabilize the psychotic disorder and may reduce the use of substances as well. Regarding the choice of antipsychotic, a meta-analysis of 19 randomized controlled trials found some evidence of superiority for clozapine in the reduction of substance use, whereas risperidone and olanzapine reduced craving (Krause *et al.* 2019). Pharmacological treatment of alcohol and substance use disorders should also be utilized. The following approaches have been studied in schizophrenia: 1) disulfiram for co-occurring alcohol use disorder (note that use requires monitoring in patients with schizophrenia); 2) naltrexone for co-occurring alcohol use disorder; 3) the tricyclic antidepressants desipramine and imipramine for comorbid cocaine use disorder; 4) buprenorphine or methadone for opioid use disorder; and 5) NRT, bupropion, and varenicline for tobacco use disorder (for reviews, see Akerman *et al.* 2014 and Pratt *et al.* 2020; for opioid use disorder, see Lamont *et al.* 2020).

Depression

Schizophrenia is often associated with depressive states ranging from dysphoria to major depressive disorder (Blum *et al.* 2015; Siris 2000; Upthegrove *et al.* 2017). A meta-analysis of cross-sectional studies demonstrated that 35.5% of inpatients and 25.8% of outpatients had current depression, as assessed with the Calgary Depression

Scale for Schizophrenia (Li *et al.* 2020), whereas the lifetime prevalence of depression in schizophrenia is as high as 50%. Depression in schizophrenia is a risk factor for suicide and an indicator of poorer outcomes (Hawton *et al.* 2005).

Major depressive disorder in individuals with schizophrenia must be carefully differentiated from classic negative symptoms such as alogia and blunted affect, antipsychotic medication-induced dysphoria occurring with potent D_2 receptor blockade, parkinsonian EPS, and demoralization that may occur when patients struggle with illness-related symptoms and disability. Shared features of negative symptoms and depression may include anhedonia, avolition, social ambivalence, and anergia (Krynicki *et al.* 2018; McGlashan and Carpenter 1976). Use of the Calgary Depression Scale for Schizophrenia helps to establish a diagnosis of major depressive disorder, as it focuses on symptoms specific to the disorder, including worthlessness, hopelessness, feelings of guilt, and suicidal thinking (Addington *et al.* 1996).

Treatment of major depressive disorder in patients with schizophrenia may include both psychopharmacological and psychosocial interventions (Ceskova 2020; Hasan *et al.* 2015). Because depression symptoms may presage an increase in psychosis and also may occur with psychosis in schizophrenia, pharmacological treatment with antipsychotic medication should be optimized first. Most of the second-generation antipsychotics are more effective than placebo for reducing depression symptoms, whereas first-generation agents are not (Huhn *et al.* 2019). Consequently, in those treated with a first-generation antipsychotic, the dosage may be reduced or the medication changed to a second-generation antipsychotic. However, an episode of major depressive disorder that develops after the remission of psychosis may require the addition of an antidepressant. A meta-analysis demonstrated antidepressant effects for trazodone, duloxetine, sertraline, and amitriptyline (Helfer *et al.* 2016). In addition, SSRIs as a group were effective (seven trials, with 422 participants; standardized mean difference = -0.48 [95% CI: -0.84 to -0.11]; $P = 0.01$).

Other approaches may also be helpful. Early evidence suggests a possible role for the use of adjunctive omega-3 polyunsaturated fatty acids (Pawelczyk *et al.* 2016; Robinson *et al.* 2019). Psychosocial interventions such as CBT (Jones *et al.* 2012) and physical exercise (Dauwan *et al.* 2016) can improve depression and well-being. Severe depression may be treated with repetitive transcranial magnetic stimulation or electroconvulsive therapy, both effective treatments for unipolar depression with some evidence of benefit in the treatment of severe depression in those with schizophrenia (Ali *et al.* 2019; Ceskova 2020).

Suicide

Suicide is a major contributor to decreased life expectancy in people with schizophrenia, who have approximately a 5% lifetime risk of completed suicide (Hor and Taylor 2010; Palmer *et al.* 2005). The risk of suicide is highest among young adults in the early stages of the illness and continues over the life span (Olfson *et al.* 2021). Among hospitalized patients, the risk of suicide peaks immediately upon admission and shortly after discharge. Nearly 50% of people with schizophrenia attempt suicide during their lifetime.

The strongest risk factors for suicide include a previous history of suicide attempts, ideation, and history of self-harm as well as symptoms of depression and hopelessness, positive symptoms of psychosis, anxiety and insomnia, and alcohol or drug abuse in schizophrenia at any age (Hor and Taylor 2010; Popovic *et al.* 2014) and in first-episode psychosis (Bornheimer *et al.* 2021; Iyer *et al.* 2021). In contrast with general population risk factors, being intelligent with good premorbid functioning, high insight, and high personal hopes and expectations are risk factors for suicide in schizophrenia (Bornheimer *et al.* 2021; Fazel *et al.* 2014). Population-level studies have demonstrated that absence of medication treatment is associated with a higher rate of suicide compared with treatment with antipsychotic medication (adjusted relative risk = 37.4 [95% CI, 5.1 to 276]) (Tiihonen *et al.* 2006).

In mitigating suicide risk, the treating clinician should regularly assess for suicide risk and protective factors (Popovic *et al.* 2014). Antipsychotic therapy plays a crucial role in the prevention of suicide by treating psychosis and depression symptoms. Several studies have demonstrated the efficacy of clozapine over other drugs for managing suicidality in patients with schizophrenia (Meltzer *et al.* 2003; Taipale *et al.* 2021). Other second-generation antipsychotics may also have antisuicide effects, although the evidence is not as robust (Barak *et al.* 2004). For patients with concurrent depression, antidepressants added to antipsychotics decrease depression (Helfer *et al.* 2016) and risk of suicide (Haukka *et al.* 2008).

Electroconvulsive therapy may be helpful for high-risk patients (Pompili *et al.* 2013).

Patients who present with suicidal thoughts or behavior may require hospital care at times of high symptom acuity and close follow-up with intensive outreach and family involvement after discharge. Ward safety measures, substance use disorder and mood disorder treatment, and interventions to improve medication adherence address suicide risk factors. Psychosocial interventions for schizophrenia that directly address suicide (e.g., CBT) have been shown to reduce suicidal thoughts and behaviors in these patients (Bornheimer *et al.* 2020).

Obsessive-Compulsive Symptoms

Obsessive-compulsive symptoms (OCSs) occur in 10%-64% of patients with schizophrenia (Wehbe *et al.* 2019). Several national cohort studies demonstrate that individuals with OCSs or OCD are at a substantially elevated risk for the development of a psychotic spectrum disorder and vice versa (e.g., Meier *et al.* 2014), consistent with the substantial overlap in risk genes for the two disorders (Lee *et al.* 2019). OCSs or OCD can occur before, during, or after onset of psychosis as well as in the context of antipsychotic use, particularly clozapine (Sharma and Reddy 2019). Some neurocognitive deficits are common to both disorders, including difficulties with attentional set-shifting and executive functioning (Sahoo *et al.* 2018; Schirmbeck *et al.* 2013). Although OCSs may be difficult to distinguish from delusions, they are important to identify because they may indicate greater impairment that may be responsive to tailored treatment approaches (Faragian *et al.* 2012; Wehbe *et al.* 2019). Therapies used for OCD can be helpful in treating OCSs in individuals with schizophrenia, including serotonergic agents and CBT (Sharma and Reddy 2019).

Conclusion and Future Directions

Although antidopaminergic medications continue to play a major role in the treatment of the positive symptoms of schizophrenia, other mechanisms of action continue to be explored in addition to novel approaches for negative and neurocognitive symptoms. Recent drug development efforts include serotonin type 2A receptor antagonists, muscarinic agonists, TAAR-1 agonists, and D-amino acid oxidase inhibitors. Early clinical trials of muscarinic agonists have demonstrated some efficacy for psychosis, with an apparent lack of metabolic or neurological adverse events but substantial gastrointestinal side effects (Brannan *et al.* 2021). TAAR-1 agonists may be efficacious for negative symptoms, with predominantly somnolence and gastrointestinal adverse events (Koblan *et al.* 2020). If approved, agents with novel mechanisms and advantageous side-effect profiles could improve the balance of benefits over risks, potentially improving treatment adherence and overall outcomes for patients with schizophrenia.

In addition to recent pharmacological advances, other novel approaches are being explored. Real-time functional MRI neurofeedback has resulted in improved symptoms and amelioration of neural network abnormalities in the brain (Bauer *et al.* 2020; Humpston *et al.* 2020; Okano *et al.* 2020). Novel psychosocial approaches, including computerized cognitive remediation, may be of benefit in treating cognitive impairment in schizophrenia (Bowie *et al.* 2020). Mobile health interventions to improve illness management are showing promise (Buck *et al.* 2021; Chivilgina *et al.* 2020). Such interventions could improve treatment access and lead to better outcomes.

Further progress is expected in the development of treatments for prodromal schizophrenia, with the goal of improving symptoms and delaying or preventing conversion to the full expression of the illness. As new treatments for the negative and cognitive systems of schizophrenia emerge, these therapeutics may also have a role in the treatment of prodromal symptoms and perhaps the prevention of schizophrenia.

CHAPTER 54

Treatment of Substance Use Disorders

Brian J. Sherman, Ph.D.
Karen J. Hartwell, M.D.
Aimee L. McRae-Clark, Pharm.D.
Alexandra Herron, B.A.
Kathleen T. Brady, M.D., Ph.D.

Substance use disorders are common in the United States. In 2019, approximately 57.2 million people (or 21% of the U.S. population) age 12 years or older reported past-year illicit drug use, with 8.3 million (3%) reporting at least one illicit drug use disorder and approximately 27 million reporting daily cigarette use (Substance Abuse and Mental Health Services Administration 2020). Therefore, many Americans are directly affected by substance use disorders, and millions more are affected through family or friends or through the societal costs associated with these disorders. The cost to society is astronomical, with annual hospital costs alone from emergency department visits and inpatient hospitalizations exceeding $13 billion in 2017 (Peterson *et al.* 2021). In 2017, the overall economic burden of opioid use disorders and opioid overdose deaths was estimated to be as high as $1.01 trillion, in large measure due to the value of life lost, lost health-related quality of life, lost productivity, and costs related to health care, treatment, and criminal justice (Florence *et al.* 2021).

Fortunately, there have been major advances in psychotherapeutic and pharmacotherapeutic treatments for substance use disorders. Recent advances in neurobiology have helped to identify major brain circuitry and neurotransmitter systems involved in substance use disorders, allowing for the development of treatments that more specifically target the systems and regions involved in addictive processes. Unfortunately, despite these new developments in medication treatments, medications are

often underused in the treatment of substance use disorders. For example, a large comparison effectiveness study of approximately 41,000 individuals with opioid use disorder reported that only 15% received treatment with one of the FDA-approved medications, although buprenorphine and methadone have been shown to reduce the risk of overdose compared with behavioral interventions and no treatment (Wakeman *et al.* 2020). The lack of access to lifesaving medications for opioid use disorder is a crucial public health issue, given the recent Centers for Disease Control and Prevention (CDC) provisional report indicating a 30% increase in annual drug overdose deaths since the beginning of the 2020 COVID-19 pandemic--largely driven by high-potency synthetic opioids such as fentanyl (Kariisa *et al.* 2022). There are many potential reasons for this increase, including the fact that much of the addiction treatment system has "grown up" outside of traditional medicine, so medications are sometimes not considered in treatment planning. In addition, many treatment programs still do not have the necessary medical personnel to evaluate patients for the appropriateness of medication treatment and prescribe it as needed. Many insurance plans provide little coverage for medications to treat substance use disorders. Broader education of physicians concerning recognition and pharmacological treatment of substance use disorders is clearly needed.

In this chapter, we focus on pharmacotherapeutic treatments for substance use disorders, but we also discuss important advances made in psychotherapeutic and behavioral treatments for these disorders. Although pharmacotherapeutics are an important and sometimes neglected part of the treatment armamentarium, medications alone are rarely sufficient for the treatment of substance use disorders and should be accompanied by comprehensive treatment planning and psychosocial treatment.

In terms of behavioral and psychosocial treatments, a meta-analysis of 34 well-controlled trials of psychosocial therapies included studies of contingency management, relapse prevention, cognitive-behavioral therapy (CBT), and combinations of CBT and contingency management. Contingency management treatments had the lowest dropout rates (< 30%), followed by CBT and combined psychosocial treatments. Treatment involving relapse prevention techniques led to the highest rate of abstinence (39%), and greater time in treatment was related to positive outcomes (Dutra *et al.* 2008). Another study found that CBT, 12-step facilitation, and brief motivational therapy were all efficacious in the treatment of DSM-IV alcohol dependence (American Psychiatric Association 1994; Project MATCH Research Group 1997). In addition, substance use disorders are truly complex and are influenced by biological and psychological factors as well as environmental circumstances. One study comparing standard methadone services with methadone services enhanced by on-site access to medical-psychiatric, employment, and family therapy found that individuals receiving enhanced services showed significantly better outcomes across several functional domains (McLellan *et al.* 1993).

Opioid Use Disorder

Opioid overdose deaths remain one of the most dramatic and deadly public health issues faced in the United States. Over the last 15 years, deaths due to opioid overdose exceeded 500,000, and declines in overall U.S. life expectancy are partially explained by this increase in overdose mortality (Hedegaard *et al.* 2020). This devastating situation has been worsened by the COVID-19 pandemic, and the estimated 70,000 opioid overdose deaths recorded during 2020 mark a 27% increase compared to estimates for 2019, according to preliminary data from the CDC National Center for Health Statistics. Overall, provisional data indicate that more than 109,000 drug overdose deaths were recorded in 2022, the largest number ever recorded in a 12-month period (National Center for health Statistics 2023).

There are three FDA-approved medications for the treatment of opioid use disorder (methadone, buprenorphine, and naltrexone), one recently approved for the treatment of opioid withdrawal symptoms (lofexidine), and one approved for the reversal of opioid overdose (naloxone). All three treatment agents for opioid use disorder bind to m-opioid receptors, but they differ in their pharmacokinetic and pharmacodynamic properties, intrinsic activity at the receptor, and mechanism of action.

Withdrawal and Detoxification

Opioid withdrawal is classified by DSM-5 (American Psychiatric Association 2013) as a condition in which a patient exhibits at least three of the following symptoms after cessation or reduction of opioid use: dysphoric mood; nausea or vomiting; muscle aches; lacrimation or rhinorrhea; pupillary dilation, piloerection, or sweating; diarrhea; yawning; fever; or insomnia. Treating opioid withdrawal (detoxification) has traditionally involved short-term substitution therapy followed by abstinence. Opioid withdrawal can begin within 8-12 hours of last use and generally peaks at 24-72 hours, with acute symptoms resolving within 5-7 days; however, the time course is dependent on the half-life of the agent being used. A protracted abstinence syndrome may continue for an additional 6-8 months and includes dysphoria, fatigue, insomnia, and irritability (Martin and Jasinski 1969). Full (methadone) and partial (buprenorphine) opioid agonists and a-adrenergic agents have been used for detoxification. If an individual is not placed on long-standing medication therapy, they are tapered off the medications over the course of 1-4 weeks and encouraged to remain abstinent with continued psychosocial treatment.

In a study comparing taper regimens of 1, 2, and 4 weeks in 70 adults with prescription opioid use disorder, Sigmon *et al.* (2013) found that patients who received the 4-week taper fared better on all outcomes. The 4-week taper group showed greater abstinence rates at week 5 (63% vs. 29% vs. 29%) and week 12 (50% vs. 16% vs. 20%) compared with the 2-and 1-

week taper groups. respectively. The 4-week taper group also had more responders, better retention, and greater post-taper naltrexone ingestion. In a multisite trial, Woody *et al.* (2008) examined taper durations in 152 youths (ages 15-21 years) with opioid use disorder who were randomly assigned to 12 weeks of buprenorphine-naloxone treatment or a 14-day detoxification protocol. Compared with youths receiving the 14-day detoxification regimen, those receiving the 12-week treatment had significantly fewer positive opioid urine test results and higher retention over the 12-week study; however, there were no between-group differences on any outcome measures at 6, 9, and 12 months after treatment. In general, longer taper durations are associated with higher abstinence rates and greater retention in treatment (Dunn *et al.* 2011). Furthermore, a systematic Cochrane Review reported that across studies, heroin-dependent adults who received methadone for detoxification only showed greater illicit heroin use and worse retention compared with those who received methadone for both detoxification and maintenance (Mattick *et al.* 2009).

a_2 Agonists (e.g., clonidine, lofexidine, and guanfacine) have long been used in the treatment of opioid withdrawal. In a Cochrane Review of 26 randomized controlled trials (RCTs) including 1,728 patients, Gowing *et al.* (2014) found that a_2 agonists were more effective than placebo in treating symptoms of opioid withdrawal but caused more adverse events such as hypotension. Whereas lofexidine has been approved for the treatment of opioid withdrawal symptoms in the United Kingdom since 1992, it was only recently approved in the United States for this indication (U.S. Department of Health and Human Services 2018). In a large, multicenter FDA registration trial for the treatment of opioid withdrawal (Fishman *et al.* 2019), participants were assigned to placebo or one of two lofexidine dosages (2.16 or 2.66 mg/day). Although the magnitude of the decrease in opioid withdrawal scores was small, there was a significant difference between lofexidine and placebo, and the authors concluded that lofexidine was safe and effective for the treatment of opioid withdrawal. Three small trials compared clonidine and lofexidine for opioid withdrawal symptoms.

The two agents showed similar efficacy, with more hypotension associated with clonidine (Gowing *et al.* 2014).

Several studies have compared detoxification with a-adrenergic agents to opioid agonist detoxification. Some studies have been unsuccessful or have shown no difference between groups (Gold *et al.* 1978, 1980; Ling *et al.* 2005), and a systematic review found side effects with a-adrenergic agents to be a significant issue (Gowing *et al.* 2003). One RCT (Law *et al.* 2017) compared the combination treatments of buprenorphine-naloxone and methadone-lofexidine for outpatient stabilization and detoxification. All participants showed a rapid reduction in withdrawal symptoms, but the methadone-lofexidine group experienced less craving and greater withdrawal symptoms. In another 14-week trial, clonidine used in conjunction with buprenorphine was associated with a longer duration of opioid abstinence than buprenorphine alone (Kowalczyk *et al.* 2015). The exploration of a-adrenergic agents as adjuncts to opioid agonists in detoxification warrants further investigation.

Rapid detoxification procedures also have been developed, including 1) rapid withdrawal induction with naltrexone, followed by high doses of clonidine and benzodiazepines to attenuate associated symptoms; and 2) rapid withdrawal under general anesthesia, with administration of numerous and varied medications to manage symptoms. These methods generally are not recommended, and rapid withdrawal under general anesthesia has been associated with multiple deaths within 72 hours (~ 3 days) of the procedure (Whittington *et al.* 2000). Although detoxification is important, rapidity should not be emphasized. Given the chronic, relapsing nature of opioid use disorders, first-line treatment has shifted toward lengthier taper durations and maintenance therapy combined with relapse prevention counseling.

Medication-Assisted Treatment

Medication-assisted treatment refers to the use of medications in combination with counseling and behavioral therapies and has demonstrated efficacy in treating opioid use disorder and in achieving sustained recovery (Mattick *et al.* 2014). In the following section, the three medication-assisted treatment modalities (methadone, buprenorphine, and naltrexone) are described.

Methadone

Methadone is a full opioid agonist with high affinity for the m opioid receptor, a long half-life, and delayed steady-state efficacy. Methadone was initially introduced in the United States in 1947, and has been regulated by the federal government as a treatment for opioid use disorder since 1972. Methadone maintenance treatment (MMT) involves closely monitored daily administration by licensed physicians at federally regulated treatment centers. Patients must attend clinic daily unless they earn take-home privileges for meeting clinic criteria such as employment and long-term abstinence. To be started on MMT, patients must be at least age 18 years and must have had an opioid use disorder for at least 1 year. MMT has been the focus of numerous clinical trials, which collectively indicate that it clearly reduces illicit opioid use and improves treatment retention (Fullerton *et al.* 2014; Mattick *et al.* 2009). MMT also has been associated with decreased mortality (Gunne and Gronbladh 1981; Kinlock *et al.* 2007), reduced nonopioid drug use (Faggiano *et al.* 2003), and decreased drug-related HIV risk behaviors (Sees *et al.* 2000). Psychosocial counseling focuses on lifestyle changes (McLellan *et al.* 1993), and interventions such as contingency contracting and voucher incentives can significantly improve outcomes of individuals receiving MMT (Brooner *et al.* 2007).

Initial dosing should begin with methadone 10-20 mg. If withdrawal symptoms are not adequately suppressed within 1 hour, additional medication may be required but should not exceed 30 mg in the first day and 40 mg in the first 3 days. Once withdrawal symptoms are stabilized, dosing can be increased to 100 mg or higher for tolerant individuals. With appropriate administration and adherence, methadone is generally safe. However, methadone-associated risks such as respiratory depression, corrected QT interval prolongation, and sudden death require acute monitoring and led to a 2006 physician safety alert from the FDA. The Substance Abuse and Mental Health Services Administration also issued recommendations for physicians who provide MMT, which include notifying patients of potential cardiac complications, screening patients for cardiac conditions, and, when indicated, conducting a pretreatment and 1-month electrocardiogram (Center for Substance Abuse Treatment 2005).

Buprenorphine

Buprenorphine is a partial opioid agonist with high affinity for the m opioid receptor. Buprenorphine suppresses opioid withdrawal and craving, reduces illicit opioid use, and can block exogenous opioid effects, including respiratory depression (Coe *et al.* 2019). Although buprenorphine also binds the d opioid receptor and is a high-affinity k opioid receptor antagonist, these actions are not likely to play a role in the use of buprenorphine in the treatment of opioid use disorder. When buprenorphine was initially approved, only physicians were allowed to prescribe it to treat opioid use disorder following an 8-hour training and approval from the U.S. Department of Health and Human Services. In 2016, the Comprehensive Addiction Recovery Act permitted nurse practitioners and physician assistants to obtain a waiver to prescribe buprenorphine following a 24-hour training and U.S. Department of Health and Human Services approval, with the goal of increasing access to treatment (Andrilla *et al.* 2018). There are limitations on the number of patients that can be seen depending on the practitioner's degree, experience, and treatment setting.

Both a buprenorphine tablet and a combined buprenorphine and naloxone film for sublingual administration were approved by the FDA in 2002 for the office-based treatment of opioid use disorder. The incorporation of naloxone in buprenorphine products was designed to decrease misuse of these products via intranasal and intravenous routes of administration. Naloxone is a high-affinity m opioid receptor antagonist with a short half-life and rapid dissociation (~ 6.5 min) from the m opioid receptor. When buprenorphine-naloxone is ingested via prescribed routes, naloxone is inert due to poor oral and sublingual bioavailability; however, when taken by the intranasal or intravenous route, naloxone is bioavailable and can precipitate withdrawal.

Given its high affinity and slow dissociation, buprenorphine may induce acute withdrawal if receptors are bound by a full agonist at the time of administration. To avoid precipitating withdrawal, physicians should wait until the patient is experiencing withdrawal symptoms to begin induction with buprenorphine. Initial dosing usually begins with 2-4 mg, which, if well tolerated, can be followed by an additional 2-4 mg approximately 8 hours later. Many patients will require a 24-to 32-mg maintenance dose, but others can be maintained with 16 mg or less once their symptoms are stabilized.

Early trials of buprenorphine established its efficacy in treating opioid use disorders. In a 25-week RCT comparing buprenorphine and methadone, investigators found the two medications to be equally effective in reducing opioid use and retaining participants in treatment (Johnson *et al.* 1992). A systematic Cochrane review evaluated evidence comparing buprenorphine maintenance with MMT and placebo (Mattick *et al.* 2014). Fixed-dose results suggested that compared with placebo, buprenorphine improved treatment retention at any dose but suppressed illicit opioid use only at doses of 16 mg or higher. Buprenorphine did not differ in treatment retention or suppression of opiate use at medium or high doses (7-15 or 16 mg) compared with methadone (40-85 or 85 mg), although low-dose methadone (40 mg) was associated with better retention than low-dose buprenorphine (2-6 mg). Studies using flexible dosing reported that buprenorphine retained fewer participants compared with methadone; however, among those retained in treatment, no difference in the suppression of opioid use was seen.

Weiss *et al.* (2011) conducted a two-phase study with 653 participants and examined brief and extended buprenorphine-naloxone treatment for prescription opioid dependence. Brief treatment included a 2-week stabilization phase, followed by a 2-week taper and an 8-week postmedication follow-up assessment (12-week treatment). The extended treatment condition included 12 weeks of buprenorphine-naloxone treatment, followed by a 4-week taper and an 8-week postmedication follow-up (24-week treatment). Extended treatment produced more successful outcomes, but only while patients were maintained on buprenorphine-naloxone; at the 8-week postmedication follow-up, there were significant reductions in treatment success rates.

Long-acting buprenorphine formulations. Further efforts to reduce diversion, improve adherence, and enhance outcomes include the development of a subcutaneous buprenorphine implant (Probuphine; Titan), which was approved by the FDA in 2016. Probuphine requires an office-based procedure for insertion and removal by trained personnel. The implant consists of four rods, each containing buprenorphine 80 mg (total 320 mg). Studies demonstrated that the implant is superior to placebo and equivalent to sublingual buprenorphine at suppressing withdrawal, decreasing craving, and reducing illicit opioid use (Ling *et al.* 2010; Rosenthal *et al.* 2013, 2016). Implant-site adverse events occurred in 23% (Rosenthal *et al.* 2016) to 56.5% (Ling *et al.* 2010) of subjects. In the outpatient trials, there were no adverse events related to respiratory depression or overdose in the persons receiving implants.

In 2017, the FDA approved a subcutaneous buprenorphine injection (Sublocade) designed for monthly administration that is now available in 100-and 300-mg doses. In trials evaluating the efficacy of the depot to reduce withdrawal, craving, and illicit opioid use, participants with opioid use disorder were inducted onto sublingual buprenorphine for up to 2 weeks and then randomly assigned to six once-monthly injections of 1) depot 300 mg, 2) two 300-mg doses followed by four 100-mg doses, 3) or matched placebo injections (Coe *et al.* 2019). Significantly more patients receiving either active dosing regimen provided illicit opioid-negative urine samples on at least 80% of testing days compared with placebo (28.4% vs. 2% for active dosing vs. placebo). There were no differences in efficacy between the two dosing regimens, but adverse events were more frequent with the higher dose. These findings suggested that the lower dosing regimen is likely appropriate for most patients. Secondary analyses suggested that certain subpopulations (e.g., people who inject drugs) may benefit from the higher-dose regimen.

In 2018, the FDA approved a second injectable, extended-release buprenorphine product that can be given once monthly or once weekly (Brixadi; Braeburn) for the treatment of opioid use disorder (U.S. Food and

Drug Administration 2018). Brixadi demonstrated noninferiority compared with daily sublingual buprenorphine-naloxone in terms of responder rate and superiority to sublingual buprenorphine-naloxone in the percentage of negative opioid urine samples from weeks 4-24. Brixadi is the only injectable buprenorphine studied against standard of care (sublingual buprenorphine-naloxone), with no opioid overdoses in patients receiving Brixadi during clinical trials (Ling *et al.* 2019).

Naltrexone

Naltrexone is a m opioid antagonist that blocks the receptor for 24-72 hours (depending on dose), preventing the experience of drug-induced euphoria. The medication was introduced in addiction treatment in the 1970s as an orally administered nonaddictive medication, with the hope of wide acceptance and effectiveness. However, adherence rates in opioid use disorder are generally low, and overdose due to relapse in previously tolerant individuals poses a serious risk for oral naltrexone use. A Cochrane review reported that most trials with oral naltrexone demonstrate poor outcomes compared with placebo, no treatment, or other pharmacological treatment (Minozzi *et al.* 2011).

Extended-release injectable naltrexone. Extended-release injectable naltrexone is administered in a monthly 380-mg intramuscular injection. The seminal study was a 24-week RCT conducted in Russia with 250 participants (Krupitsky *et al.* 2013), in which participants receiving extended-release naltrexone had a significantly greater median proportion of confirmed weeks abstinent compared with placebo (90% vs. 35%), higher median numbers of opioid-free days (99.2% vs. 60.4%), longer treatment retention (> 168 vs. 96 days), and greater reductions in craving scores. However, extended-release naltrexone inductions can be challenging because of the need for complete detoxification from opioids before starting extended-release naltrexone in order to avoid precipitating withdrawal. In a recent study in opioid use disorder, 72% of participants were successfully inducted onto extended-release naltrexone compared with 94% successfully inducted onto buprenorphine (Lee *et al.* 2018). Once patients were inducted, the relapse rate was comparable for the extended-release naltrexone and buprenorphine groups (52% vs. 56% [Lee *et al.* 2018]).

Recommendations on Medication-Assisted Treatment for Opioid Use Disorder

In summary, methadone seems to be more effective than low-dose buprenorphine in retaining patients in treatment. However, methadone is no different from buprenorphine at higher, fixed doses in terms of treatment retention or suppression of opioid use. Furthermore, the fact that buprenorphine can be obtained via prescription in an office-based practice gives patients and providers more flexibility than is allowed by the regulations surrounding methadone prescribing. The long-acting formulations of buprenorphine have the advantage of improving adherence and decreasing diversion, misuse, and accidental poisoning. However, there is practitioner burden involved in medication administration, particularly for Probuphine. According to a Substance Abuse and Mental Health Services Administration (2012) advisory, subgroups most likely to benefit from extended-release naltrexone include patients whose symptoms were treated unsuccessfully with methadone or buprenorphine, those who prefer a less stigmatizing and more convenient alternative, those opposed to agonist therapy, highly motivated individuals, and adolescents or young adults for whom access to treatment facilities is often restricted by government regulations. In general, oral naltrexone is not recommended because of poor adherence and should be reserved for highly motivated patients who are willing to comply with strategies to improve adherence (e.g., observed dosing).

Novel Medication Approaches to Opioid Use Disorder

N-Methyl-ᴅ-aspartate receptor antagonists, such as memantine, ketamine, dextromethorphan, and phencyclidine, prevent the development of tolerance to and dependence on the analgesic effects of morphine in rodents and play a role in associative opioid reward learning (Herman *et al.* 1995). A recent meta-analysis revealed 19 clinical trials of *N*-methyl-D-aspartate antagonists of varying quality in individuals with opioid use disorder (Fluyau *et al.* 2020). Across the trials, there was moderate evidence showing that these agents reduce opioid withdrawal and modest evidence indicating that they reduce opioid use and craving. Ibogaine, an indole alkaloid derived from root bark, is another novel agent that has been explored in the treatment of opioid use disorder. Ibogaine is classified as a hallucinogen in the United States, but it is unregulated in many countries where it is used in religious and cultural ceremonies (Mash 2018). Animal studies have demonstrated that ibogaine can decrease opioid self-administration. Several uncontrolled observational studies suggest that ibogaine may treat symptoms of opioid withdrawal and have some value in relapse prevention

(Brown and Alper 2018). An exploratory human laboratory trial found that acute administration of cannabidiol (CBD) decreased both craving and anxiety induced by the presentation of opioid-related cues in individuals with opioid use disorder (Hurd *et al.* 2019). These compounds are of interest because they represent novel therapeutic mechanisms, but there is much work to be done in exploring their potential in opioid use disorder treatment, and unintended adverse consequences (e.g., abuse potential) must be considered.

Overdose Treatment

The increasing opioid overdose death rate has led to substantial efforts to expand access to and education about naloxone, an opioid antagonist that is capable of rapidly reversing opioid overdose by decoupling opioids from the opioid receptor and inducing acute withdrawal. Naloxone can be administered via injection or nasal spray and either route is equally effective in reversing opioid overdose. However, naloxone is short acting; if an individual has overdosed on a long-acting opioid, consecutive doses of naloxone may be required and the odds of requiring rescue dosing are higher with the nasal spray than with the injection (Yousefifard *et al.* 2020). Naloxone access has increased in the past 10 years, with multiple states passing immunity laws that enable physicians to prescribe the drug or civilians and first responders to administer the drug without fear of civil, criminal, or professional liability (National Conference of State Legislatures 2017).

Cannabis Use Disorder

Cannabis remains the most commonly used illicit drug in the United States, with more than 31 million past-month users (Substance Abuse and Mental Health Services Administration 2020). One in five individuals who report lifetime cannabis use meet criteria for cannabis use disorder, and age-based prevalence rates of current cannabis use disorder are 5.8% of adults ages 18-25 years, 1.0% of adults age 26 or older, and 4.6% of adolescents ages 12-17 years (Compton *et al.* 2019; Substance Abuse and Mental Health Services Administration (2020). Cannabis use disorder is associated with significant physical and mental health consequences (Hall 2015; Volkow *et al.* 2014), and a higher severity of cannabis use disorder is associated with an exponential increase in treatment utilization (Hasin *et al.* 2016; Kerridge *et al.* 2018). Despite increasing demand, there is a dearth of effective treatment options for cannabis use disorder. Psychosocial interventions show modest efficacy of limited durability, and despite numerous pharmacotherapy trials targeting a range of mechanisms, there are no FDA-approved medications for cannabis use disorder (Kondo *et al.* 2020; Sherman and McRae-Clark 2016). This section discusses pharmacotherapy trials for the treatment of cannabis use disorder, including the most recent and promising developments in the field.

Psychotropic Medications

Early clinical trials investigated a range of psychotropic medications, including antidepressants, anxiolytics, antipsychotics, and mood stabilizers. Certain pharmacotherapeutic agents showed initial promise, particularly in co-occurring affective disorders, whereas others showed deleterious effects. None have demonstrated efficacy for treating cannabis use disorder in large-scale clinical trials.

Antidepressants and Anxiolytics

Serotonin reuptake inhibitors (including selective serotonin reuptake inhibitors) were some of the first candidate medications, as serotonin is implicated in neuropsychiatric behaviors and disorders including anxiety, depression, appetite, cognition, and substance use disorders. A secondary analysis of placebo-controlled trials of fluoxetine for alcohol-dependent adults with depression found reductions in cannabis use frequency and quantity among a subsample of comorbid cannabis users, suggesting the potential utility of serotonin reuptake inhibitors in cannabis use disorder (Cornelius *et al.* 1999). However, this finding was not supported in a subsequent trial in adolescents and young adults with co-occurring depression and cannabis use disorder (Cornelius *et al.* 2010). Subsequent trials of escitalopram (Weinstein *et al.* 2014) and vilazodone (McRae-Clark *et al.* 2016) also failed to improve cannabis outcomes. The nonbenzodiazepine anxiolytic buspirone also drew early attention in a pilot study, which found greater point-prevalence abstinence among treatment completers (McRae-Clark *et al.* 2009). However, a large follow-up trial in adults with cannabis use disorder found no treatment effect; of note, a gender effect indicated worse outcomes among women compared with men (McRae-Clark *et al.* 2015).

Medications that target the dopaminergic and noradrenergic systems have also been studied, as dopamine plays a critical role in mesolimbic reward processing (Tanda *et al.* 1997) and chronic cannabis use is associated with dopaminergic system dysfunction (Bloomfield *et al.* 2016). The catechol O-methyltransferase inhibitor entacapone, which targets synaptic dopamine regulation, was tested in one open-label trial of 36 cannabis-dependent adults (Shafa 2009); cannabis craving was reduced, but cannabis use data were not reported and no follow-up trials have been published. Bupropion, which inhibits the reuptake of norepinephrine and dopamine and has some limited serotonergic activity, was investigated in an RCT exploring sustained-release bupropion, nefazodone, and placebo in

106 cannabis-dependent adults, with no effect of either medication on cannabis use or withdrawal (Carpenter *et al.* 2009). A 12-week clinical trial of venlafaxine for co-occurring cannabis use disorder and depressive disorders engendered higher D-9-tetrahydrocannabinol (THC) levels and lower abstinence rates and did not reduce depressive symptoms compared with placebo (Levin *et al.* 2013). Moreover, the venlafaxine group reported more severe cannabis withdrawal symptoms (Kelly *et al.* 2014).

Cognitive Enhancers

Atomoxetine is a norepinephrine reuptake inhibitor that is FDA approved for the treatment of ADHD. An open-label study of atomoxetine found trend-level reductions in self-reported cannabis use, but no significant increase in biologically confirmed abstinence (Tirado *et al.* 2008). A second study investigated atomoxetine for cannabis use disorder in adults with ADHD and found a reduction in ADHD symptoms but no effect on cannabis use outcomes (McRae-Clark *et al.* 2010).

Mood Stabilizers

Two mood-stabilizing medications have been investigated for treatment of cannabis use disorder. In a 12-week clinical trial with 25 participants, divalproex did not perform better than placebo in achieving cannabis abstinence, reducing use, or decreasing withdrawal symptoms (Levin *et al.* 2004). In another study, lithium reduced cannabis withdrawal in rats by stimulating oxytocin release (Cui *et al.* 2001). In an RCT with 38 adults with cannabis use disorder, lithium did not improve abstinence rates or reduce cannabis use, although it did reduce withdrawal-related symptoms, including nightmares, appetite, and stomachache (Johnston *et al.* 2014).

Anticonvulsants

Gabapentin, an indirect modulator of the GABAergic system, is FDA approved for the treatment of epileptic seizures and neuropathic pain. A small pilot study reported that gabapentin reduced cannabis use and withdrawal symptoms (Mason *et al.* 2012); however, results posted from a larger follow-up study do not suggest an impact on cannabis abstinence (ClinicalTrials.gov NCT00974376). A placebo-controlled trial of topiramate, which acts on GABAergic and glutamatergic systems, in adolescent cannabis users also reported negative results (Miranda *et al.* 2017).

Glutamatergic Modulators

The glutamatergic modulator *N*-acetylcysteine (NAC) received recent attention in two randomized, placebo-controlled clinical trials of NAC versus placebo for the treatment of cannabis use disorder. The first study in 116 young adults ages 13-21 years found significantly greater point-prevalence abstinence rates among participants receiving NAC 1,200 mg/day compared with matching placebo (40.9% vs. 27.2%, respectively) (Gray *et al.* 2012). However, in a subsequent RCT in 302 adults, there were no differences between the NAC and placebo groups in cannabis abstinence, treatment retention, or medication adherence (Gray *et al.* 2017).

Cannabinoids

The endocannabinoid system is involved in a number of neurobiological processes, including reward processing, homeostasis, sleep, feeding, emotion regulation, and stress response, and has been identified as a critical target in the treatment of cannabis use disorder (Martin and McRae-Clark 2020). THC is the primary intoxicating component of the *Cannabis sativa* plant and produces its effects via binding at the cannabinoid CB_1 receptor. Agonist therapy with natural and synthetic THC derivatives has been investigated with promising results.

Dronabinol and Nabilone

Dronabinol is an oral THC formulation that acts as a direct CB_1 agonist. Initial inpatient and outpatient human laboratory studies found that dronabinol reduced withdrawal symptoms (Budney *et al.* 2007; Haney *et al.* 2004) but was associated with abuse liability and decrements in cognitive performance (Vandrey *et al.* 2013). Subsequent cannabis cessation clinical trials found no effect on cannabis abstinence. In a 12-week RCT, dronabinol (40 mg/day) reduced withdrawal symptoms and improved retention but did not produce greater reductions in cannabis use (Levin *et al.* 2011). Another placebo-controlled trial of dronabinol (60 mg/day) combined with lofexidine found no differences from placebo in cannabis use, withdrawal, or retention (Levin *et al.* 2016). Nabilone is a synthetic cannabinoid with potential as an agonist replacement therapy. In a human laboratory study, nabilone more effectively reduced cannabis withdrawal symptoms in adults with cannabis use disorder compared with placebo (Haney *et al.* 2013). However, a randomized controlled pilot study did not demonstrate efficacy of nabilone in achieving cannabis abstinence (Hill *et al.* 2017). Given concerns about abuse liability and more recent promising options, dronabinol and nabilone demonstrate low potential for cannabis cessation treatment.

Nabiximols

Agonist replacement therapy using nabiximols, which combines THC with CBD and terpenoids derived from the cannabis plant, has shown promise in recent trials. In an initial study comparing a 6-day course of nabiximols with placebo in 51 inpatients with cannabis use disorder (Allsop *et al.* 2014), nabiximols reduced cannabis withdrawal severity and improved treatment retention but did not significantly reduce cannabis use or time to relapse following treatment. In a 12-week RCT, nabiximols reduced cannabis craving compared with placebo but did not show a treatment effect on cannabis use or withdrawal symptoms (Trigo *et al.* 2018). More recently, a larger RCT with 128 participants demonstrated a reduction in self-reported cannabis use days during treatment with nabiximols (Lintzeris *et al.* 2019) and at a 3-month follow-up (Lintzeris *et al.* 2020), although cannabis withdrawal and psychosocial outcomes did not differ between groups.

Cannabidiol

Human laboratory studies suggest that CBD may mitigate adverse acute effects of THC (for review, see Freeman *et al.* 2019), which has led to investigations of CBD as a potential pharmacotherapeutic agent. In a 10-week open-label trial of CBD 200 mg among 20 heavy cannabis users, participants showed decreased depressive and psychotic symptoms and improved cognitive function after treatment compared with baseline; however, they also reported increased euphoria when smoking cannabis (Solowij *et al.* 2018). A recent 4-week adaptive trial with 48 participants found that compared with placebo, 400-and 800-mg doses of CBD resulted in lower THC/creatinine ratios and an increase in self-reported abstinence, whereas a 200-mg dose did not produce a treatment effect (Freeman *et al.* 2020). Although these studies have notable limitations, including the lack of a control condition, small sample sizes, and brief treatment durations, further investigation of CBD is warranted.

Fatty Acid Amide Hydrolase Inhibitors

Fatty acid amide hydrolase (FAAH) inhibitors are a promising area of medication development for the treatment of cannabis use disorder. The FAAH enzyme breaks down the endocannabinoid anandamide, and evidence suggests that potentiating endocannabinoid signaling through inhibition of anandamide breakdown may reduce withdrawal symptoms (Falenski *et al.* 2010) and decrease risk for cannabis use disorder (Boileau *et al.* 2016). A recent randomized clinical trial in 70 men with DSM-IV cannabis dependence investigated a 3-week course of the FAAH inhibitor PF-04457845 compared with placebo following an inpatient detoxification period (D'Souza *et al.* 2019). Compared with the 24 placebo-treated participants, the 46 participants who received PF-04457845 demonstrated fewer withdrawal symptoms and better sleep during the inpatient phase and lower urinary THC levels and reduced cannabis use during the outpatient phase. A multisite clinical trial of PF-04457845 is currently underway (NCT03386487).

To date, the FDA has not approved any pharmacotherapies for the treatment of cannabis use disorder. Although early studies of psychotropic medications yielded few positive effects, more recent studies of potential agonist replacement therapies, FAAH inhibitors, and CBD have shown promise and may warrant additional investigation.

Tobacco Use Disorder

Despite early declines, the 2019 National Survey on Drug Use and Health reported that 58.1 million people (or 21% of the population ages [?] 12 years) were current users of a tobacco product, with 26.8 million reporting daily cigarette smoking (Substance Abuse and Mental Health Services Administration 2020). Few tobacco users are successful in permanently quitting in their initial attempt; most consume tobacco for many years and cycle through periods of abstinence and relapse. Failure to grasp the chronic nature of tobacco use disorders can lead to discouragement among health care providers and impede treatment over time. In 2018, although about 55% of adult smokers reported a past-year quit attempt, only 7.5% successfully quit (Creamer *et al.* 2019). Counseling strategies, including in-person counseling, telephone quitlines, and self-help materials, have a small but important effect in achieving smoking cessation. Telephone counseling is readily available in the United States through the publicly funded quitline 1-800-QUIT-NOW (1-800-784-8669). A pooled estimate of 47 trials indicated that increasing the amount of behavioral support increased the chance of successful smoking cessation by 10%-25% (Stead *et al.* 2015).

Current practice guidelines recommend the use of an effective medication at every quit attempt unless medically contraindicated or within special populations (e.g., pregnant women, adolescents) for which there is limited evidence of effectiveness (Fiore *et al.* 2008). Seven first-line medications are safe, effective, and FDA approved for smoking cessation, including nicotine replacement therapies (NRTs; patch, gum, lozenge, nasal spray, and inhaler), sustained-release bupropion, and varenicline. Generally, cessation medications double the quit rate relative to placebo (20% vs. 10% [Cahill *et al.* 2013]).

Nicotine Replacement Therapies

NRTs partially replace the nicotine obtained from cigarettes and are intended to aid in quitting by reducing the severity of nicotine withdrawal. A 2012 Cochrane review of 150 studies reported that NRT increased cessation rates to 17% compared with 10% with placebo (number needed to treat = 15 [Stead *et al.* 2012]). Nicotine patches, gum, and lozenges are available over the counter. The nicotine inhaler and nasal spray are prescription medications. Nicotine from the gum and lozenge is absorbed through the buccal mucosa. Nicotine from the inhaler and nasal spray is absorbed through the oropharynx and nasal mucosa, respectively. The nicotine patch, which is designed for skin absorption, has the advantage of once-a-day application and has higher adherence rates as a result.

Nicotine gum is available in 2-and 4-mg doses, with 4-mg nicotine gum recommended for individuals who smoke 25 or more cigarettes a day. Smokers should be instructed to use 1 piece of gum every 1-2 hours (maximum of 24 pieces per day) for the first 6 weeks and to taper the frequency over the next 6 weeks. The gum should be slowly chewed until a "peppery" taste emerges and then "parked" between the cheek and the gum to facilitate absorption. The gum should be intermittently chewed slowly and parked until the taste dissipates, typically in about 30 minutes. Common side effects include hiccups, dyspepsia, and jaw discomfort.

Nicotine lozenges are available in 2-and 4-mg doses, with the 4-mg dose recommended for individuals who smoke their first cigarette within 30 minutes of awakening. In general, at least 9 lozenges per day should be used for the first 6 weeks, with a maximum of 20 lozenges per day. Common adverse effects include hiccups, nausea, and heartburn.

The nicotine patch has the advantage of daily dosing, thus enhancing compliance. For patients who smoke more than 10 cigarettes a day, a standard course includes 21 mg for 6 weeks, followed by 14 mg for 2 weeks, and then 7 mg for 2 weeks. Approximately 50% of patients will experience a mild local skin reaction (Fiore *et al.* 2008), which requires discontinuation in about 5% of patients. Rotating the site daily can help prevent skin reactions. Insomnia and vivid dreams also may occur; removing the patch before bedtime can reduce the disruption in sleep.

Most of the nicotine (4 mg) in an inhaler cartridge is deposited in the mouth, with less than 5% reaching the lower respiratory tract. Puffing intensively (80 deep inhalations over 20 minutes) leads to the absorption of approximately 2 mg. Recommended dosing is 6-16 cartridges a day for 3 months, followed by tapering over the subsequent 3 months. Coughing and rhinitis are common side effects. Exacerbation of reactive airway disease can occur.

The nicotine nasal spray produces the highest nicotine level compared with other forms of NRT. The first dose is 0.5 mg administered in each nostril (total 1 mg) per hour as needed, with a minimum of 8 doses and a maximum of 40 doses per day. The recommended duration of therapy is 3-6 months. Most patients experience varying degrees of nasal irritation. Other common side effects include transient changes in sense of taste and smell. Severe reactive airway disease is a contraindication.

Of note, the use of NRT is not an independent risk factor for acute myocardial infarction. However, NRT should be used with caution in patients who have unstable angina pectoris or severe arrhythmias and who have experienced myocardial infarction within the past 2 weeks. Some smokers may benefit from a longer course of NRT treatment. Schnoll *et al.* (2015) compared 8 weeks (standard), 24 weeks (extended), and 52 weeks (maintenance) of nicotine patch treatment in combination with 12 weeks of smoking cessation counseling. At 6 months, 22% of participants in the standard treatment group were abstinent compared with 27% in the extended and maintenance groups.

Sustained-Release Bupropion

In the late 1990s, the sustained-release formulation of bupropion was FDA approved for smoking cessation and marketed under the trade name Zyban (GlaxoSmithKline). Sustained-release bupropion is an antidepressant with noradrenergic and dopaminergic effects and antagonist action at the nicotinic acetylcholine receptor. In a recent Cochrane review, bupropion was found with high certainty to increase long-term smoking cessation rates for at least 6 months (risk ratio, 1.64) compared with placebo; bupropion may work by blocking nicotine effects, relieving withdrawal, or decreasing depressed mood (Howes *et al.* 2020). A standard sustained-release bupropion course begins with one 150-mg tablet taken by mouth once a day for 3 days, at which point the dosage is increased to one tablet taken by mouth twice a day (separated by at least 8 hours) for 7-12 weeks. The tobacco quit date is 1 week after starting medication. If the treatment is successful, some patients benefit from continued treatment for up to 6 months to prevent relapse.

Sustained-release bupropion is generally well tolerated but lowers the seizure threshold, and seizures are estimated to occur in 1 of 1,000 treated patients (Hughes *et al.* 2014). Contraindications include seizure disorders, eating disorders, and monoamine oxidase inhibitor use within 14 days.

Varenicline

Varenicline is a partial agonist at the a4b2 nicotinic receptor that relieves symptoms of nicotine withdrawal and blocks nicotine from attaching to the receptor, thus reducing the rewarding properties of smoking (Coe *et al.* 2005). Numerous controlled studies support the efficacy of varenicline for smoking cessation. Two 12-week RCTs including more than 2,000 participants (Gonzales *et al.* 2006; Jorenby *et al.* 2006) compared varenicline, bupropion, and placebo. The investigators found that rates of continuous abstinence for the last month of the treatment phase were 44% for varenicline, 30% for bupropion, and 18% for placebo. Continuous abstinence rates at 1 year were 23%, 14.6%, and 10.3% for varenicline, bupropion, and placebo, respectively (Jorenby *et al.* 2006). A standard course is typically 0.5 mg/day for 3 days, then 0.5 mg bid for 4 days, and then 1 mg bid with food. The target quit date is 1 week after starting varenicline. If clinically warranted, the initial total 12-week course can be continued for an additional 12 weeks if initial treatment is successful.

Black Box Warning Removal

In 2009, a black box warning was added to the packaging information for both varenicline and bupropion after an FDA review of postmarketing data concluded that these medications could potentially increase the risk of depression, suicidality, agitation, worsening preexisting psychiatric illnesses, and changes in behavior (U.S. Food and Drug Administration 2009). These warnings call for close monitoring for symptoms or changes in behavior. A 2015 meta-analysis of 39 RCTs with approximately 11,000 participants found no evidence of an increased risk of suicide, suicide attempts, suicidal thoughts, depression, aggression, or death in participants taking varenicline compared with placebo (Thomas *et al.* 2015), confirming results of an earlier meta-analysis by Gibbons and Mann (2013) that included 17 RCTs conducted by Pfizer and a large dataset from the U.S. Department of Defense. In December 2016, the FDA determined that the risk of these serious side effects on mood, behavior, and thinking was lower than expected and the black box warning was removed.

Combination Therapies

A Cochrane review found insufficient evidence to establish whether combined bupropion and NRT result in superior quit rates compared with NRT alone. Previous research has indicated that combination NRT (patch and lozenge) increased quit rates compared with either placebo or monotherapy (Piper *et al.* 2009).

Varenicline combined with bupropion has been investigated in several RCTs. One showed greater 4-week smoking abstinence for weeks 8-11 with combination therapy than with monotherapy (39.8% vs. 25.9%; odds ratio, 1.89 [95% CI, 1.07-3.35]) (Rose and Behm 2014). Ebbert *et al.* (2014) found greater prolonged abstinence (53% vs. 43% at 12 weeks and 37% vs. 28% at 26 weeks) in the combination group compared with varenicline plus placebo, although the results were not significant at 52 weeks. In a study by Rose and Behm (2014), smokers who used the nicotine patch and did not reduce smoking were randomly assigned to 12 weeks of varenicline and sustained-release bupropion or varenicline plus placebo. Participants receiving the combination had significantly higher abstinence rates compared with the varenicline plus placebo group (40% vs. 26%). The combination treatment was significantly more effective in male individuals and highly dependent smokers. Despite these early promising reports, a recent Cochrane meta-analysis found insufficient evidence to determine whether the combination of varenicline and bupropion produced quit rates superior to those seen with varenicline alone (Howes *et al.* 2020).

Second-Line Medications

Second-line medications should be considered on a case-by-case basis if first-line medications (alone or in combination) are ineffective or contraindicated. Several medications are effective but have a more limited role because of potential side effects and lack of FDA approval for smoking cessation. Medications in this category include clonidine and nortriptyline (Fiore *et al.* 2008).

Special Populations

Women Who Are Pregnant or Trying to Conceive

The harmful effects of smoking during pregnancy are well known and include small-for-gestational-age neonates, stillbirth, preterm birth, and placenta previa (Jauniaux and Burton 2007). Current guidelines recommend the use of in-person psychosocial strategies exceeding minimal advice to quit smoking. Although quitting smoking during the first trimester will produce the greatest benefit, quitting at any time is beneficial. In a recent meta-analysis that excluded potentially biased, noncontrolled RCTs, NRT was no more effective than placebo (Coleman *et al.* 2015). Evidence is insufficient to recommend the use of bupropion or varenicline during pregnancy.

Children and Adolescents

Tobacco use is typically initiated and established during adolescence (U.S. Department of Health and Human Services 2012). The annual Monitoring the Future survey has shown a long and significant decline in adolescent cigarette smoking since the mid-1990s, with the lack of a further decrease first occurring in 2020 (Johnston *et al.* 2021). The most critical finding of the latest survey is that vaping has doubled or tripled among eighth-, tenth-, and twelfth-graders. For example, among twelfth-graders, the 30-day prevalence rate of nicotine vaping rose from 11% in 2017 to 26% in 2019 (Johnston *et al.* 2021). Current treatment guidelines recommend that clinicians assess tobacco use in children and adolescents and strongly recommend abstinence. Psychosocial interventions, especially

those that contain CBT components, were efficacious in the short term for the treatment of adolescent smokers (Simon *et al.* 2015). Contingency management and motivational interviewing have shown some effectiveness as stand-alone treatments, and strategies that include elements of the transtheoretical model of change also have shown promise.

Individuals With Comorbid Psychiatric Disorders

Despite the significant decline in smoking rates in the general population, comparable declines in smoking rates among smokers with psychiatric disorders have not been realized. According to combined data from the 2019 National Survey on Drug Use and Health, 21% of adults had some form of mental illness in the past year; of these, 27% were current smokers compared with 16% of adults without mental illness (Substance Abuse and Mental Health Services Administration 2020). Unfortunately, individuals with mental illnesses are frequently excluded from clinical studies focused on the treatment of tobacco use disorders, and smoking cessation therapies are not routinely offered to patients with severe mental illness. Mental health professionals commonly have permissive attitudes toward smoking and mistakenly assume that patients with comorbid psychiatric and substance use disorders are not interested in quitting (Sheals *et al.* 2016). These attitudes and misconceptions undermine the provision of smoking cessation interventions in these populations.

Evidence shows that smoking cessation therapies are both effective and well tolerated in populations with severe mental illness. A recent large multisite, global smoking cessation trial of more than 4,000 participants compared the efficacy and safety of NRT, bupropion, and varenicline in individuals with mood, psychotic, and anxiety disorders (Evins *et al.* 2019). Neither varenicline nor bupropion was associated with a higher rate of severe neuropsychiatric adverse events relative to NRT or placebo. Similar to previous studies of smokers without a mental disorder, varenicline was superior to bupropion, NRT, and placebo and both bupropion and NRT were superior to placebo. These results indicate that pharmacotherapy should be considered in planning smoking quit attempts in psychiatric populations. Clinical practice guidelines recommend a treatment duration of 12 weeks, but more recent evidence indicates that maintenance pharmacotherapy for 1 year may improve sustained abstinence rates in individuals with schizophrenia spectrum disorders (Evins and Cather 2015).

Admission to a smoke-free psychiatric hospital is a natural opportunity to provide smoking cessation treatment. In a previous study, daily smokers with and without an intention to quit were recruited from several locked psychiatric units and randomly assigned to interventions that included tailored counseling with an emphasis on readiness to quit and NRT availability after discharge (Schuck *et al.* 2016). An impressive 76% of eligible smokers enrolled; of these, 88% requested study-provided NRT. Those with more severe psychiatric symptoms were more likely to request NRT after hospitalization ($P < 0.01$). Participants who requested NRT at discharge were more likely to make a 24-hour quit attempt and to self-report abstinence at the 1-week follow-up (54% with a quit attempt, 14% abstinent) compared with participants who did not request NRT at discharge (25% with a quit attempt, 4% abstinent) ($P < 0.05$).

Individuals With Comorbid Substance Use Disorders

Individuals with other substance use disorders smoke at a higher rate than those without other substance use disorders (56% vs. 21%) and have lower quit rates (23% vs. 51%)

(Streck *et al.* 2020). Importantly, individuals receiving treatment for substance use disorders are more likely to die from smoking-related illnesses than from complications from drug use (Baca and Yahne 2009). However, many individuals receiving substance use disorder treatment continue to smoke despite achieving abstinence from alcohol and drugs (McClure *et al.* 2015). Current treatment guidelines recommend that patients with substance use disorders be offered smoking cessation treatment (Fiore *et al.* 2008). It has been suggested that varenicline may be the most effective treatment for alcohol use disorders and comorbid alcohol and tobacco use disorders, because alcohol produces activation in the mesolimbic pathway through its effects on nicotinic acetylcholine receptors (Soderpalm *et al.* 2000). Varenicline has been reported to decrease alcohol craving and consumption in smoking cessation trials (Fucito *et al.* 2011; Mitchell *et al.* 2012).

In a review of smoking cessation interventions during substance use disorder treatment, a variety of pharmacotherapy and behavioral treatment options significantly improved smoking outcomes (Thurgood *et al.* 2015). Smokers with opioid use disorders may present a particular challenge. Smoking rates among individuals with opioid use disorder are fourfold higher than among the general population, and recent pharmacotherapy outcomes have been disappointing and typically worse than those seen in the general population (Miller and Sigmon 2015). Additional research to understand the relationship between tobacco and substance use disorders is warranted, given that smoking cessation has the potential to improve the morbidity and mortality associated with these common disorders.

Stimulant Use Disorder

The search for a pharmacotherapeutic treatment for cocaine and amphetamine use disorders has been extremely active over the last 20 years, with controlled trials of antidepressants, anticonvulsants, dopamine agonists and antagonists, and many other agents. Unfortunately, many medications that show promise in animal models of stimulant dependence and/or positive outcomes in small uncontrolled trials fail to decrease drug use by objective measures in larger controlled trials. In addition, many clinical trials in stimulant-dependent individuals have high dropout rates and medication noncompliance. To date, there are no FDA-approved medications for the treatment of cocaine or amphetamine use disorders; however, the medications discussed in this section have shown promise, often in subgroups of individuals studied.

Agonist Replacement Strategies

As discussed in previous sections, agonist replacement therapies are effective in nicotine and opioid use disorders. For this reason, the focus of many studies in stimulant use disorder treatment has been agonist replacement in which a pharmacologically similar agent is substituted for the stimulant of abuse. An ideal agonist replacement therapy for stimulant dependence should share some pharmacological and behavioral effects with cocaine or amphetamine but have less abuse potential. Unfortunately, many agents that have shown promise do not meet these criteria.

Methylphenidate, an agent that produces effects similar to those of cocaine at the dopamine transporter and is approved for the treatment of ADHD, has been tested in cocaine and amphetamine use disorder in patients with and without ADHD. Although the results of these studies have generally been negative (Stoops and Rush 2013), findings have been mixed in individuals with ADHD, with positive results seen in cocaine and amphetamine use disorder with a dosage of 60 mg/day (Konstenius *et al.* 2010; Levin *et al.* 2007) and negative results seen in cocaine use disorder with 80-90 mg/day (Levin *et al.* 2006; Schubiner *et al.* 2002). Several trials have indicated that D-amphetamine and methamphetamine can decrease cocaine use in individuals with cocaine use disorder (Grabowski *et al.* 2001, 2004; Mooney *et al.* 2009; Shearer *et al.* 2003). However, trials of D-amphetamine in amphetamine use disorder have been negative (Galloway *et al.* 2011; Longo *et al.* 2010). These studies suggest that stimulant replacement warrants further investigation, but it must be noted that the abuse and diversion potential of methylphenidate and amphetamines limits the potential widespread utility of this approach (Stoops *et al.* 2004).

Other Pharmacotherapeutic Agents

Bupropion

Bupropion, an antidepressant with dopaminergic activity, has been tested in multiple clinical trials in both cocaine and methamphetamine use disorders. The results were largely mixed, but bupropion seems to have some efficacy when combined with consistent behavioral treatment for patients with cocaine use disorder (Poling *et al.* 2006) and in methamphetamine users with less severe methamphetamine use disorder (Elkashef *et al.* 2008; Shoptaw *et al.* 2008). A recent double-blind, placebo-controlled trial explored the use of extended-release injectable naltrexone plus oral extended-release bupropion in methamphetamine use disorder in a two-stage design, in which individuals taking placebo who did not have a response in the first 6 weeks were randomly reassigned to treatment (Trivedi *et al.* 2021). Response was defined as at least three of four methamphetamine-negative urine samples at the end of stage 1 or 2. The weighted average response across the two stages was 13.6% with naltrexone-bupropion and 2.5% with placebo ($P < 0.001$). Although the response rate for active treatment was low, there was a significant difference from placebo.

Disulfiram

In addition to its effects on alcohol metabolism, disulfiram blocks the enzymatic degradation of both cocaine and dopamine. Investigators have hypothesized that increased dopamine levels may help improve hedonic tone (i.e., sense of well-being, pleasure, or contentment) in individuals with cocaine use disorder, and increased cocaine levels have been shown to increase cocaine-related anxiety and dysphoria in individuals pretreated with disulfiram (Hameedi *et al.* 1995). Regardless of the mechanism, four clinical trials to date have reported that disulfiram reduces cocaine use in individuals with cocaine use disorder (Carroll *et al.* 2004; George *et al.*

2000). Given these results, disulfiram should be considered in the treatment of cocaine use disorder as long as the individual is willing to remain alcohol free and understands the potential for increased toxicity with cocaine use.

Modafinil

Modafinil, a glutamatergic agent that is FDA approved for narcolepsy, has been tested in both cocaine and amphetamine use disorders. Although initial trials were positive (Dackis *et al.* 2005), subsequent trials reported that efficacy was limited to individuals

who did not have a history of alcohol use disorder and to men (Anderson *et al.* 2009; Dackis *et al.* 2012). Trials of modafinil are ongoing, but the medication is well tolerated and may be useful in reducing cocaine withdrawal symptoms and helping some individuals attain abstinence (Malcolm *et al.* 2002).

Topiramate

There have also been several promising studies with topiramate, an anticonvulsant agent that has shown promise in alcohol use disorder. In one placebo-controlled trial of cocaine dependence, topiramate-treated subjects were more likely than placebo-treated subjects to achieve 3 weeks of continuous abstinence and to be rated as clinically improved (Kampman *et al.* 2004).

Vigabatrin

Vigabatrin (g-vinyl-GABA), an anticonvulsant that increases GABA neurotransmission by inhibiting GABA transaminase, showed promise in several open-label trials in cocaine and methamphetamine use disorders. A placebo-controlled trial reported higher rates of abstinence (assessed by self-report and urine drug screen) in the vigabatrin-treated group with cocaine use disorder than in the placebo group (Brodie *et al.* 2009), whereas a multisite trial (Somoza *et al.* 2013) found no difference in any outcomes in individuals with cocaine use disorder taking vigabatrin compared with placebo. However, compliance with vigabatrin was low in the trial by Somoza *et al.* (2013), which calls the negative results into question.

N-Acetylcysteine

N-Acetylcysteine is a glutamatergic agent that also has shown consistent positive results in animal models of cocaine use disorder (Baker *et al.* 2003). Although an initial pilot study with a crossover design showed promise in cocaine use disorder (LaRowe *et al.* 2006), a follow-up double-blind, placebo-controlled trial (LaRowe *et al.* 2013) reported no difference between two doses of *N*-acetylcysteine and placebo on any outcome measures. However, a reduction in cocaine-positive urine drug screens was seen in a small subset of individuals who were abstinent at initiation of study drug, suggesting that *N*-acetylcysteine may be more efficacious in preventing relapse than in initiating abstinence. Further studies are required to assess this possibility.

Conclusion and Future Directions

Effective pharmacological treatments are available for opioid and tobacco use disorders, but studies suggest that these treatments are underutilized and there is clearly room for improvement in terms of efficacy. Exploration of medications with novel mechanisms of action, including hallucinogens, is ongoing for both tobacco and opioids, but much work remains to be done. The search for medication treatment for stimulant use disorders remains an active area of research, with a wide range of agents being tested across hundreds of clinical trials. To date, the FDA has not approved any pharmacotherapies for the treatment of cannabis use disorder, but recent studies of potential agonist replacement therapies, FAAH inhibitors, and CBD have shown promise and may warrant additional investigation. Given the devastating personal and societal effects of substance-related disorders, pharmacotherapy should be considered when appropriate as part of a comprehensive treatment plan.

CHAPTER 55

Treatment of Alcohol Use Disorder

Barbara J. Mason, Ph.D.
Eva Ritvo, M.D.
Antonello Bonci, M.D.

Introduction

Epidemiology of Alcohol Misuse

A 2021 national survey found that approximately 28.6 million Americans (11.3%) met DSM-5 (American Psychiatric Association 2013) criteria for alcohol use disorder (AUD) (Substance Abuse and Mental Health Services Administration 2021a). Alcohol misuse was estimated to cost the U.S. economy about $249 billion annually, on the basis of factors such as lost productivity, health care expenses, and law enforcement costs (U.S. Department of Health and Human Services 2016). About three-quarters of alcohol-related costs to U.S. society are due to *binge drinking*--defined as a pattern of drinking that raises the blood alcohol concentration (BAC) to 0.08% (i.e., 0.08 grams of alcohol per deciliter (g/dL) or higher (Figure 55-1). This pattern corresponds to consumption of 4 or more (for women) or 5 or more (for men) *standard drinks* (Figure 55-2) within a 2-hour time frame. Such alcohol misuse is associated with harm to drinkers and those around them, increasing the risk of motor vehicle crashes, unsafe sexual behavior, suicidality, alcohol overdose, and fetal alcohol spectrum disorders.

Chronic *heavy drinking*--defined as regular consumption of 4 or more drinks per day or more than 7 drinks per week for women, and 5 or more drinks per day or more than 14 drinks per week for men--is causally associated with various cancers, heart disease, liver disease, depression, and cognitive deficits (National Institute on Alcohol Abuse and Alcoholism 2023). Alcohol is responsible for the deaths of more than 140,000 Americans annually (Centers for Disease Control and Prevention 2020; National Institute on Alcohol Abuse and Alcoholism 2023), with over 82,000 deaths due to chronic conditions such as liver disease, and over 58,000 deaths due to acute causes such as accidents. Alcohol consumption accounts for about half of all liver disease in the United States (Yoon and Chen 2018), and more than 10,000 people die from drunk driving every year, including victims who were not using alcohol (National Center for Statistics and Analysis 2020). Worldwide, alcohol misuse is the seventh leading risk factor for premature death and disability (Global Burden of Disease 2016 Alcohol Collaborators 2016).

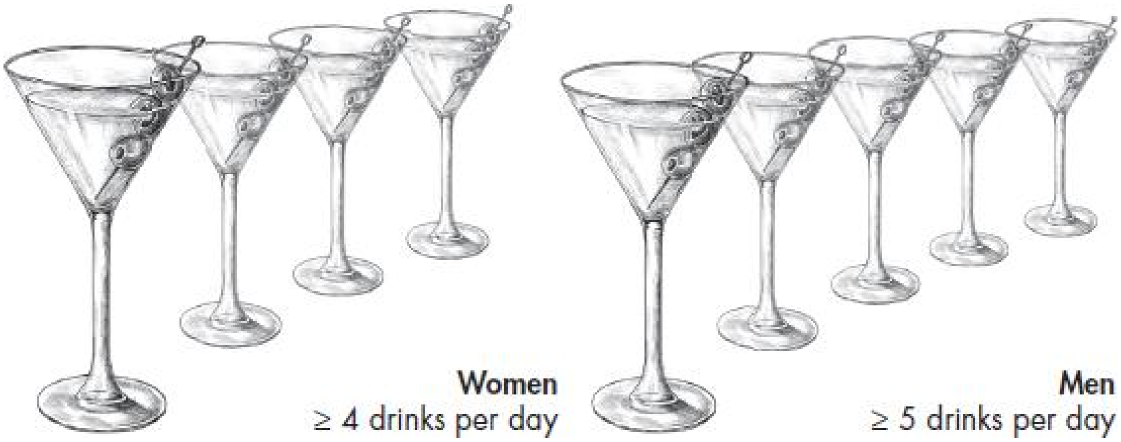

FIGURE 55-1. Heavy drinking and binge drinking.

Heavy drinking is defined as 4 or more standard drinks per day for women, and 5 or more standard drinks per day for men. *Binge drinking* is defined as a pattern of drinking that raises the blood alcohol concentration to 0.08% or higher.

Source. National Institute on Alcohol Abuse and Alcoholism (NIAAA): *Rethinking Drinking: Alcohol and Your Health* (NIH Publication No. 21-AA-3770). Bethesda, MD, NIAAA, July 2022b. Available at: https://www.niaaa.nih.gov/sites/default/files/publications/NIAAA_RethinkingDrinking.pdf. Accessed April 23, 2023.

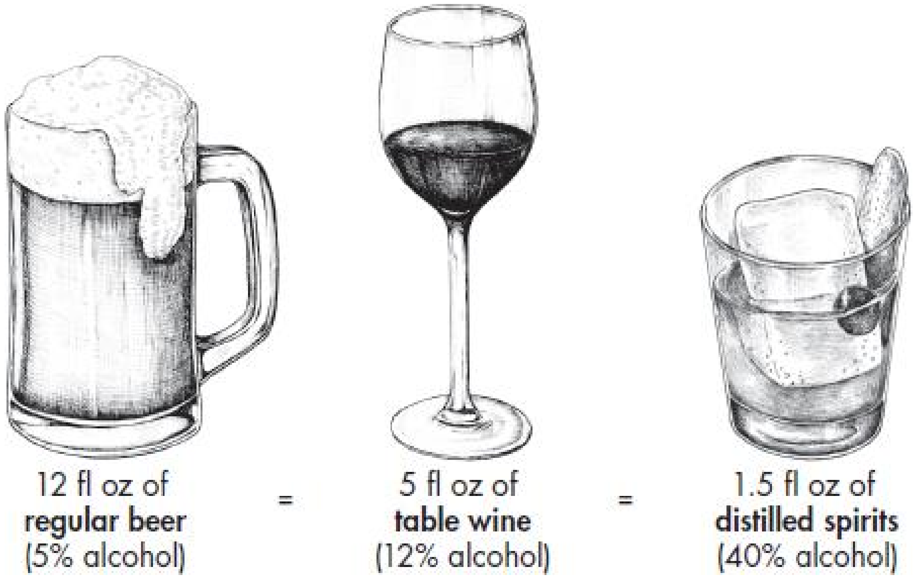

FIGURE 55-2. Standard drink equivalents.

In the United States, a *standard drink* is defined as any drink that contains about 0.6 fluid ounces, or 14 grams, of pure alcohol. This amount of alcohol roughly corresponds to 12 ounces of regular beer (usually about 5% alcohol), 5 ounces of wine (usually about 12% alcohol). and 1.5 ounces of distilled spirits (usually about 40% alcohol [i.e., 80 proof]). Although standard drink amounts are helpful for following health guidelines and monitoring alcohol use, they may not reflect customary serving sizes.

Available at: https://www.niaaa.nih.gov/sites/default/files/publications/NIAAA_RethinkingDrinking.pdf. Accessed April 23, 2023.

Detection and Diagnosis of Alcohol Use Disorder

A common reason why individuals with AUD do not seek treatment is that they are unaware that they need it (U.S. Department of Health and Human Services 2016). Individuals may never have been told that they have AUD or may not consider themselves to have a drinking problem. Underestimating the severity of one's drinking problem and overestimating one's ability to control it are associated with alcohol-induced changes in brain circuits that control incentive salience, negative affect, and executive function (Koob and Le Moal 1997; U.S. Department of Health and Human Services 2016). These factors underscore the importance of adequate screening and accurate diagnosis as a first step in treating AUD. The Screening, Brief Intervention, and Referral to Treatment (SBIRT; Substance Abuse and Mental Health

Services Administration 2013) model is an evidence-based approach to early detection and intervention for those at risk for developing AUD. The SBIRT model makes efficient use of a clinician's time, which may be particularly important when multiple potential disorders require assessment. For example, a single standardized screening question was found to effectively detect unhealthy alcohol use: "How many times in the past year have you had X or more drinks in a day?" where X is 5 for men and 4 for women, and a response of 1 or greater is considered positive (Smith *et al.* 2009). Quick questions on drinking quantity and frequency do not provide a diagnosis of AUD. However, a positive screen can serve as a signal that further evaluation is warranted because chronic heavy alcohol use may lead to the development of AUD. For individuals found to be drinking at an unhealthy level, the SBIRT model stipulates that a brief intervention using motivational interviewing be provided. A Cochrane Review concluded that brief interventions were more effective in reducing alcohol consumption compared with control conditions at follow-up 1 year after the brief intervention (mean difference -20 g/week), with comparable efficacy found in men and women (Beyer *et al.* 2019). If clinical follow-up shows that the brief intervention was ineffective in reducing alcohol use, evidence-based pharmacological and behavioral treatment for AUD should be provided.

A diagnosis of AUD is based on positive findings on at least 2 of 11 DSM-5 criteria, as shown in Table 55-1. DSM-5 combines earlier diagnostic criteria for alcohol abuse and dependence under the term *alcohol use disorder*, with severity modifiers of *mild*, *moderate*, or *severe* based on the number of criteria met. ICD-11 (World Health Organization 2021), ICD-10 (World Health Organization 1992), and DSM-IV (American Psychiatric Association 1994) use the term *alcohol dependence* and include congruent diagnostic criteria (Degenhardt *et al.* 2019; Lago *et al.* 2016). DSM-5 criteria for AUD of moderate or greater severity were found to be essentially equivalent to DSM-IV and ICD-10 criteria for alcohol dependence (Compton *et al.* 2013). Pharmacological treatment is typically considered for alcohol dependence and AUD of moderate or greater severity. This stage of the disorder usually follows a chronic, relapsing course characterized by compulsive heavy alcohol drinking despite harmful consequences that may be mitigated by pharmacological treatment (American Psychiatric Association 2013, 2017).

TABLE 55-1. Summary of DSM-5 criteria for alcohol use disorder and ICD-11 criteria for alcohol dependence

DSM-5 criteria for alcohol use disorder (APA 2013)	ICD-11 criteria for alcohol dependence (WHO 2021)
A problematic pattern of alcohol use manifested by [?] 2 symptoms within 12 months:	A problematic pattern of alcohol use manifested by [?] 2 symptoms of impaired regulation:
1. Impaired control over use	1. Impaired control over use
2. Unsuccessful efforts to cut down or quit	2. Alcohol use prioritized over other aspects of life despite negative consequences
3. Extensive time spent drinking or recovering from drinking	3. Physiological indicators of neuroadaptation, e.g.,
4. Craving or a strong urge to use	a. tolerance
5. Use given priority over major role obligations	b. withdrawal
6. Use despite interpersonal consequences	c. use of alcohol to prevent or alleviate withdrawal
7. Activities reduced or given up due to use	Symptoms are usually present for 12 months, or 3 months if use is continuous.

Note. Pharmacological treatment is typically indicated for alcohol use disorder of moderate or greater severity and alcohol dependence. APA = American Psychiatric Association; WHO = World Health Organization.

8. Use in physically hazardous situations	
9. Use despite negative health (mental and physical) consequences	
10. Tolerance	
11. Withdrawal	
Current severity:	
Mild: 2 or 3 symptoms	
Moderate: 4 or 5 symptoms	
Severe: 6 or more symptoms	

Note. Pharmacological treatment is typically indicated for alcohol use disorder of moderate or greater severity and alcohol dependence. APA = American Psychiatric Association; WHO = World Health Organization.

Rationale for the Pharmacological Treatment of Alcohol Use Disorder

Cost-benefit studies of AUD treatment (1967-1997) have consistently found that individuals with untreated AUD utilize health care, and incur medical costs, at a rate about twice that of their age and gender cohorts who are treated for AUD (Holder 1998). Conversely, total health care costs decrease following initiation of treatment for AUD. The combination of FDA-approved medication for AUD and evidence-based behavioral therapy was found to be associated with fewer inpatient admissions and 30% lower total health care costs compared with costs of individuals not receiving medication-assisted treatment (Baser *et al.* 2011). These statistics make a compelling case for considering FDA-approved medications for all patients with AUD. Yet despite these evidence-based findings for efficacy, results from a 2019 nationally representative survey found that fewer than 3% of Americans with past-year AUD were treated with one of the medications approved by the FDA to treat AUD (Han *et al.* 2021). Meta-analyses of controlled trials of acamprosate and naltrexone showed effect sizes that were equivalent to those in meta-analyses of controlled trials of widely used antidepressants for treating major depressive episodes (Jonas *et al.* 2014; Maisel *et al.* 2013; Schalkwijk *et al.* 2014). The relative underutilization of existing effective AUD medications may be a function of factors ranging from inadequate training in this domain to the lack of a financial incentive for the pharmaceutical industry to market AUD medications that are available in inexpensive generic formulations.

Appropriate utilization of pharmacological treatment of AUD has been advanced by subspecialty certifications in addiction psychiatry and addiction medicine (Nunes *et al.* 2020) and by the publication of two important guidelines: the first report on alcohol, drugs, and health from the Office of the Surgeon General (U.S. Department of Health and Human Services 2016) and the American Psychiatric Association (APA) *Practice Guideline for the Pharmacological Treatment of Patients With Alcohol Use Disorder* (American Psychiatric Association 2017). The Surgeon General's report recommends a chronic care management approach to treating AUD that includes evidence-based behavioral and pharmacological treatment; social support services; and clinical monitoring of adverse events, medication adherence, and symptoms of relapse at each follow-up visit. The report further recommends working collaboratively with patients and their social support systems to communicate the risks and benefits of each treatment option relative to the patients' recovery goals, drug costs, and dosing schedules and ensuring that patients comprehend this information.

The APA practice guideline provides evidence-based recommendations that may facilitate appropriate prescribing of existing medications to treat AUD; it also includes recommendations for prescribing two repurposed medications, gabapentin and topiramate, to treat AUD on the basis of an evaluation of the clinical trial literature generated by academic investigators. Including evidence-based repurposed medications in the APA guideline broadens the available options for effectively treating AUD. The guideline recommends that acamprosate or naltrexone be used by individuals with moderate to severe AUD who wish to cut down on or quit drinking, who prefer medication or who have not responded to nonpharmacological treatments, and who have no contraindications to the use of these medications. These recommendations are based on large-scale meta-analyses that found that either acamprosate or naltrexone combined with counseling showed superior efficacy in increasing rates of abstinence (acamprosate, number needed to treat [NNT] = 2) or no heavy drinking (naltrexone, NNT = 12) relative to placebo administered in conjunction with counseling (Jonas *et al.* 2014). "NNT = 12" indicates that about 12 people would need to be treated to achieve a single case of no drinking or no heavy drinking. No significant difference was found between acamprosate and naltrexone for a return to any drinking or heavy drinking in meta-analyses of those trials that compared acamprosate and naltrexone (Jonas *et al.* 2014). The APA practice guideline further suggests that disulfiram

not be selected as an initial treatment for AUD, given the physiological consequences of combining this medication with alcohol. In addition, this guideline recommends that antidepressant medications not be used for the treatment of AUD, unless there is a co-occurring disorder for which these treatments are indicated. Furthermore, it is noted that the medications approved to treat AUD are not treatments for alcohol withdrawal and should be initiated only following detoxification and/or after abstinence has been established.

Pharmacological Treatment of Alcohol Withdrawal

For some individuals, pharmacological management of alcohol withdrawal symptoms may be required before pharmacological treatment of AUD can be initiated. One of the DSM-5 criteria for AUD is the emergence of acute alcohol withdrawal, with symptoms occurring within several hours to a few days of marked reduction in or abrupt cessation of alcohol intake in individuals with extended periods of heavy drinking. The DSM-5 criteria for alcohol withdrawal are met when two or more of the following eight symptoms are present and cannot be better explained by another disorder, including withdrawal from another substance: 1) autonomic hyperactivity (i.e., a pulse rate greater than 100 bpm), 2) increased hand tremor, 3) insomnia, 4) nausea or vomiting, 5) transient hallucinations, 6) psychomotor agitation, 7) anxiety, and 8) generalized tonic-clonic seizures. The Clinical Institute Withdrawal Assessment for Alcohol--Revised is a widely used scale developed to repeatedly measure the severity of these symptoms over the time course of withdrawal, with a cutoff score greater than or equal to 10 indicating withdrawal symptoms that may require medical intervention (Sullivan *et al.* 1989). Symptoms may last 4-5 days and peak within 2 days of the last drink, reflecting the relatively fast metabolism of alcohol (American Psychiatric Association 2013). If symptoms have not emerged within 2 days of the last drink or are consistently scored less than 10 on the Clinical Institute Withdrawal Assessment for Alcohol--Revised in individuals without a history of alcohol withdrawal seizures or delirium tremens, symptoms can typically be managed without medication (Holt and Tetrault 2022; Sullivan *et al.* 1989). For detailed guidance on managing alcohol withdrawal, including sample medication regimens, readers are referred to *The ASAM Clinical Practice Guideline on Alcohol Withdrawal Management* (American Society of Addiction Medicine 2020).

It is estimated that up to 10% of patients with very heavy alcohol use (e.g., > 8 drinks per day over multiple days) may develop severe withdrawal symptoms that can be life threatening and may include tonic-clonic seizures and delirium tremens (American Psychiatric Association 2013; Hoffman and Weinhouse 2022). Risk for severe withdrawal increases with age, family history or prior history of withdrawal, use of sedative-hypnotic drugs, and concurrent serious medical conditions. Inpatient treatment and close monitoring is typically warranted to mitigate the risk for severe withdrawal. Patients at risk for severe withdrawal, or those who have serious medical conditions that could increase their risk, may be given a front-loading high initial dose of benzodiazepines to prevent symptom onset or to achieve more rapid control of symptoms (Sellers *et al.* 1983). Supportive care includes correction of electrolyte imbalances and nutritional deficiencies.

Outpatient treatment can be considered for pharmacological management of patients not at risk for severe withdrawal who are cognitively intact, able to avoid alcohol and take oral medication, and willing to commit to frequent monitoring (Hayashida *et al.* 1989). Outpatient treatment can be given on a fixed tapering schedule or on a symptom-triggered dosing schedule (Hoffman and Weinhouse 2022; Saitz *et al.* 1994). A significant other can be recruited to monitor withdrawal symptoms and assist the patient in determining when a dose is indicated if symptom-targeted dosing is used. Worsening symptoms, medication misuse, or alcohol use should prompt a higher level of care. All detoxifying patients should be prescribed a multivitamin containing folate and thiamine (see also "Initiation and Monitoring of Pharmacological Treatment" section later in chapter).

Benzodiazepines are the gold standard for treating mild to moderate withdrawal symptoms (e.g., a Clinical Institute Withdrawal Assessment for Alcohol--Revised score > 10 and < 20) and preventing progression to severe alcohol withdrawal (e.g., a Clinical Institute Withdrawal Assessment for Alcohol--Revised score > 20), given their documented effectiveness and high margin of safety (Department of Veterans Affairs and Department of Defense 2021). A Cochrane Review did not find meaningful differences between individual benzodiazepines in terms of safety or efficacy for treating alcohol withdrawal (Amato *et al.* 2010). Longer-acting benzodiazepines (e.g., chlordiazepoxide) lessen the likelihood of breakthrough symptoms. Shorter-acting benzodiazepines (e.g., lorazepam or oxazepam) have fewer metabolites that depend on liver function, which reduces risk in patients with impaired hepatic function or cognitive function. Benzodiazepines are subject to misuse and should not be prescribed beyond the acute withdrawal period. Rather, patients should be engaged in a treatment plan that includes evidence-based behavioral and pharmacological treatment of AUD.

Although benzodiazepines are considered the drugs of choice for treating alcohol withdrawal, anticonvulsants have been studied as an alternative or adjunctive treatment for mild to moderate alcohol withdrawal for patients in whom the risks of benzodiazepines may outweigh benefits (e.g., those who may not have adequate monitoring available or those with abuse liability). For example, gabapentin has some advantages relative to benzodiazepines: it does not interact with alcohol, is less associated with impaired cognition or motor coordination, is not metabolized in the liver, and has low lethality in overdose (Ahmed *et al.* 2019; Mason *et al.* 2018; Myrick *et al.* 2009). These features are attractive, as alcohol detoxification is increasingly provided on an outpatient basis. Of note, comprehensive reviews have concluded that anticonvulsants should not be considered a stand-alone treatment for severe alcohol withdrawal because of their ineffectiveness in suppressing seizures related to alcohol withdrawal (Hammond *et al.* 2015; Leung *et al.* 2015). Initiating gabapentin dosage titration in conjunction with alcohol detoxification may also assist in decreasing withdrawal-related anxiety and insomnia as well as serve as a transition to longer-term relapse prevention treatment (Mason *et al.* 2018; Myrick *et al.* 2009).

FDA-Approved Medications for the Treatment of Alcohol Use Disorder

Three medications are approved by the FDA for the treatment of AUD: disulfiram (Antabuse and generic, oral), naltrexone (ReVia and generic, oral; and Vivitrol, long-acting injectable),

and acamprosate (Campral and generic, oral). Each drug has a different mechanism of action that can be understood within the cyclical framework of AUD, as illustrated in Figure 55-3.

Protracted withdrawal

FIGURE 55-3. Conceptual framework for the effects of various medications on the three major stages of the alcohol addiction cycle and the clinical stages of alcohol use disorder (AUD).

The *outer ring* depicts the clinical stages of AUD. The *inner ring* depicts the three stages of the addiction cycle.

Source. Adapted from Koob GF, Volkow ND: "Neurocircuitry of addiction." *Neuropsychopharmacology* 35(1):217-238, 2010. Copyright (c) 2010, Springer Nature. Used with permission.

Acute (up to 5 days' duration) withdrawal syndrome may emerge upon a marked reduction in or abrupt cessation of drinking and is typically followed by a protracted withdrawal phase of indeterminate duration, with a high risk of relapse to pathological drinking; the clinical phases of AUD are illustrated in the outer ring in Figure 55-3. The negative affect stage of protracted withdrawal includes symptoms of anxiety, dysphoria, and irritability (Geller 1991) and is associated with the activation of brain stress systems, in particular overexpression of corticotropin-releasing factor in the extended amygdala (Koob 2008). Such neuroadaptations extend into the preoccupation-anticipation stage of the addiction cycle (the inner ring in Figure 55-3). Dysregulation in the prefrontal cortex during the preoccupation-anticipation stage drives symptoms of craving and perpetuates residual negative emotional states and sleep disturbance. All these symptoms of protracted withdrawal have been identified as risk factors for drinking relapse (Brower *et al.* 1998; Clark *et al.* 1998; Foster and Peters 1999; Gillin *et al.* 1994; Lowman et al. 1996), and the underlying neurobiology offers a multitude of potential drug targets, as shown in Figure 55-3.

Early FDA-approved medications for AUD targeted the binge/intoxication stage by serving as either a psychological deterrent (disulfiram) or an antagonist of the reinforcing effects of alcohol (naltrexone). Acamprosate, a medication discussed later, supports abstinence through the modulation of activity in the glutamatergic system that is associated with craving and the preoccupation-anticipation stage of protracted withdrawal. Acamprosate tends to have a more benign side-effect profile and to be better tolerated than earlier medications (Mason and Heyser 2010) (Table 55-2). To date, there are no FDA-approved drugs associated with the withdrawal/negative affect stage of the addiction cycle, but repurposed drugs have been identified (e.g., gabapentin), and novel drug targets specific to this stage are under investigation and are discussed later in this chapter.

TABLE 55-2. Summary of FDA-approved medications for the treatment of alcohol use disorder

	Disulfiram (oral)	Naltrexone (oral)	Naltrexone (injectable)	Acamprosate (oral)

	Disulfiram (oral)	**Naltrexone (oral)**	**Naltrexone (injectable)**	**Acamprosate (oral)**
Primary evidence-based outcome	No drinking	No heavy drinking days	Number of heavy drinking days	No drinking
	Double-blind trials, NS [c]	NNT = 12 [d]	WMD = -4.6% [d]	NNT = 12 [d]
	Open-label trials, moderate effect size [c]	NNT = 8.6 [e]		NNT = 7.5 [e]
	Supervised administration trials, large effect size [c]			
Median trial duration	6.5 months [c]	3 months[d]	6 months[f]	6 months[d]
Standard dosing	500 mg/day weeks 1-2; 250 mg/day thereafter	One 50-mg tablet daily	One 380-mg injection monthly	Two 333-mg tablets tid
Cost per month [a]	$50	$32	$1,464	$76
Abstinence baseline	[?] 12 hours (mandatory) [b]	~ 4 days[e]	~ 7 days [b, f]	~ 6 days [e]
Medical contraindications [b]	Use of metronidazole, paraldehyde	Opioid dependence,	Opioid dependence, withdrawal, or use	Severe renal impairment (creatinin

	Disulfiram (oral)	**Naltrexone (oral)**	**Naltrexone (injectable)**	**Acamprosate (oral)**
	, alcohol-containing preparations Severe myocardial disease or coronary occlusion Psychosis	withdrawal, or use Acute hepatitis or liver failure	within 7-10 days Acute hepatitis or liver failure	e clearance [?] 30 mL/min)
Adverse events[b]	Neuritis, neuropathy, hepatitis, hepatic failure, psychosis, drowsiness, fatigue, impotence, headache, acne, allergic dermatitis, metallic/garlic aftertaste	Nausea, headache, dizziness, nervousness, fatigue, insomnia, vomiting, anxiety, somnolence, hepatic injury, hepatitis	[?] 5% and 2x placebo: vomiting, nausea, injection site reactions, muscle cramps, dizziness, syncope, somnolence, sedation, decreased appetite	[?] 3% and > placebo: diarrhea, flatulence, nausea, pain, pruritus

Note. Review each drug's package insert for full prescribing information. NNT = a statistical estimate of the number needed to treat to achieve the specified outcome in one individual; NS = not significantly different from placebo; WMD = weighted mean difference.

Disulfiram

Disulfiram was the first FDA-approved (in 1951) pharmacotherapy for AUD. It inhibits the enzyme aldehyde dehydrogenase, so that if even small amounts of alcohol are consumed, acetaldehyde quickly builds up, with rapid onset of a disulfiram-alcohol interaction that includes flushing, nausea and vomiting, changes in mental status, and multiple cardiac and respiratory symptoms that could be fatal in severe reactions. Disulfiram thus is used as a deterrent to alcohol use and should never be given to patients when in a state of alcohol intoxication or without their full knowledge. The psychological threat of the disulfiram-alcohol interaction, as opposed to the drug's pharmacodynamic properties, may be the primary mechanism of disulfiram's deterrent effect (Skinner *et al.* 2014). The fear of a disulfiram-alcohol interaction is equivalent across groups in placebo-controlled double-blind trials and mitigates against detecting disulfiram treatment effects relative to placebo. A meta-analysis of randomized open-label trials found a moderate effect of disulfiram relative to various comparison groups; the effect of disulfiram was found to be large under conditions of supervised administration (Skinner *et al.* 2014). Disulfiram tablets are taken orally each morning, starting with 500 mg/day for the first 1-2 weeks, then decreasing to 250 mg each morning thereafter. Medication adherence is a demonstrated problem with disulfiram (Fuller *et al.* 1986), and outcomes are optimized with supervised administration (e.g., by a spouse or roommate) in compliant patients (Jorgensen *et al.* 2011). Supervised administration may also be achieved via a Zoom check-in, and a Bluetooth-enabled smart pill dispenser can be used that sends notifications to avoid missed doses.

Disulfiram may be considered for patients with a clear goal of complete abstinence, who are capable of understanding the risks of an alcohol-disulfiram interaction, who have no medical contraindications, and who prefer disulfiram or have not responded to acamprosate and naltrexone (American Psychiatric Association 2017). Prior to initiating treatment with disulfiram, patients should receive a physical exam with electrocardiogram and liver function tests (LFTs). Disulfiram is medically contraindicated in patients who have had a recent myocardial infarction or coronary artery disease, or have a history of a seizure disorder, or are psychotic. It should be used with caution and enhanced monitoring in patients with a history of psychosis, as psychotic reactions have been noted. Metronidazole, paraldehyde, and alcohol-containing preparations like sertraline oral concentrate and cough syrups are contraindicated, as are alcohol-containing mouthwash, hand sanitizers, aftershaves, sauces, salad dressings, and desserts and any other food preparation that might include alcohol to avoid precipitating an alcohol-disulfiram interaction. The intensity of the interaction varies across individuals but is generally proportional to the amounts of disulfiram and alcohol ingested. The duration of the reaction ranges from 30 to 60 minutes to several hours, or as long as there is alcohol in the blood. Patients should be instructed to abstain from alcohol for at least 12 hours and have a zero BAC before taking disulfiram. They should also be advised that reactions with alcohol can occur up to 14 days after taking disulfiram.

Repeat LFTs should be obtained periodically, as elevations in hepatic enzymes--and, more rarely, potentially fatal acute hepatotoxicity--commonly occur even after months of treatment and in patients with normal baseline liver function (National Institute of Diabetes and Digestive and Kidney Diseases 2021). Patients should be instructed to seek immediate medical attention if signs and symptoms of liver toxicity occur (fatigue, weakness, persistent abdominal pain, nausea, vomiting, jaundice, or dark urine). It is suggested that patients carry a wallet card noting that they are taking disulfiram in case of medical emergency.

A meta-analysis found more serious adverse events with disulfiram than with comparison treatments (Skinner *et al.* 2014). The alcohol-disulfiram interaction has inherent risks, which some patients use to strengthen their motivation to abstain from alcohol. Many have found disulfiram to be well tolerated when taken as prescribed (Chick 1999). The potential benefit of disulfiram for appropriately selected patients who prefer this treatment has been found to outweigh the harms, in particular given the risks of continued alcohol misuse (American Psychiatric Association 2017).

Naltrexone

Naltrexone is a pure opioid receptor antagonist that was originally approved by the FDA as a treatment for opioid dependence in 1984. It was repurposed and approved by the FDA 10 years later for the treatment of alcohol dependence (oral, 1994; long-acting injectable, 2006). Opioid receptor antagonism as a treatment strategy for AUD is based on the hypothesis that if alcohol consumption is less rewarding, drinking will decrease. A reduction in the rate of heavy drinking is the positive outcome most commonly reported in clinical trials of naltrexone for the treatment of AUD (Jonas *et al.* 2014; Maisel *et al.* 2013). Problems with medication nonadherence have been noted with oral naltrexone (Volpicelli *et al.* 1997), and thus a long-acting (30-day) injectable formulation was developed. A systematic review and meta-analysis included 53 randomized controlled trials of oral naltrexone (50 mg/day) for the treatment of AUD (Jonas *et al.* 2014). The included studies involved 9,140 patients and treatment durations of 12 weeks or longer. Naltrexone was found to significantly decrease the likelihood of a return to heavy drinking (NNT = 12) and, to a lesser extent, a return to any drinking (NNT = 20). This finding replicates results from an earlier meta-analysis that found an NNT of 8.6 for a reduction in heavy drinking associated with naltrexone (Maisel *et al.* 2013). This earlier meta-analysis also assessed clinical moderators of the response to naltrexone treatment and found that about 4 days of abstinence prior to beginning treatment significantly improved the treatment response. In addition, treatment goals other than abstinence were associated with a larger effect size for reducing heavy drinking than the goal of complete abstinence. Studies of potential genetic moderators of naltrexone response have focused on m opioid receptor gene polymorphism status. Initial enthusiasm for this pharmacogenetic approach was based on secondary analyses of completed clinical trials that found patients might be more responsive if they have at least one G allele of the A118G polymorphism of *OPRM1* (Anton *et al.* 2008b; Kranzler *et al.* 2013; Oslin *et al.* 2003). However, subsequent studies found no association between genotype and naltrexone response, including a negative clinical trial that prospectively stratified patients on the basis of their *OPRM1* genotype (Oslin *et al.* 2015). A review concluded that these conflicting results do not support a role for *OPRM1* genotype determination in clinical practice (Jones *et al.* 2015).

There have been no head-to-head comparisons of the efficacy of oral versus injectable naltrexone to date. A meta-analysis of drinking outcomes among 1,926 participants in two trials examining different formulations of injectable naltrexone found no significant effects of treatment on time to return to any drinking or heavy drinking, but did find a reduction in the number of heavy drinking days (weighted mean difference [WMD], -4.6%). The trials, conducted in support of FDA approval, found a similar reduction in heavy drinking days with Vivitrol 380 mg/month, but only for men and those with 7 days of abstinence prior to randomization (Garbutt *et al.* 2005).

Any form of naltrexone treatment for AUD is contraindicated in patients who are physiologically dependent on opioids, who are in opioid withdrawal, who have used prescribed or illicit forms of opioids within 7-10 days, or who have findings on a urine drug screen (UDS) positive for opioids. The reason for these prohibitions is to avoid unintended precipitation of opioid withdrawal through the administration of an opioid antagonist. Naltrexone has the capacity to cause hepatocellular injury when used in higher than recommended dosages and is contraindicated in patients with acute hepatitis or liver failure. Naltrexone has not been evaluated in patients with severe hepatic impairment, and clinical trials of naltrexone tend to exclude patients with LFT values greater than three times the upper limit of normal. Caution is also advised when using naltrexone to treat patients with moderate to severe renal impairment because naltrexone and its primary metabolite are excreted primarily in the urine, and it has not been studied in patients with moderate or greater renal impairment.

To manage risk, baseline medical screening for naltrexone treatment may include tests of renal and hepatic function and a UDS. Repeat LFTs (alanine aminotransferase [ALT], aspartate aminotransferase [AST], gamma-glutamyltransferase [GGT]) may verify the absence of naltrexone-related hepatic enzyme abnormalities. Patients may be advised to carry a wallet card indicating they are receiving naltrexone. In the case of an emergency requiring pain management, nonopioid analgesics or regional analgesia can be used. Naltrexone will also antagonize the effects of opioid-based remedies (e.g., for coughs or diarrhea), so nonopioid-based treatments should be selected. A meta-analysis found a higher risk for discontinuation due to adverse events with naltrexone relative to placebo; common side effects included nausea, vomiting, and dizziness (Jonas *et al.* 2014). Patients receiving Vivitrol may also experience a range of injection site reactions. Patients should be advised not to drive or operate heavy machinery until they are comfortable with how the drug affects them. They should also be advised to seek medical attention if they experience symptoms of acute hepatitis (persistent stomach pain, dark urine, tiredness, yellowing of the whites of the eyes).

The majority of clinical trials of naltrexone have been 3 months in duration. Two early studies found that treatment effects were no longer significant relative to placebo 1 to 3 months after treatment (Anton *et al.* 2001; O'Malley *et al.* 1996). Given that the antagonist effect of the drug does not persist beyond drug elimination, pairing naltrexone with a coping skills/relapse prevention form of cognitive-behavioral therapy (CBT) may offer an optimal treatment strategy whereby heavy drinking is tempered pharmaceutically and behavioral therapy facilitates the lifestyle characteristic of long-term recovery (O'Malley *et al.* 1992).

Acamprosate

Acamprosate was developed in France in the 1980s and was approved by the FDA in 2004 for the maintenance of abstinence in detoxified alcohol-dependent individuals. Acamprosate is a synthetic compound with a chemical structure similar to that of GABA and the amino acid neuromodulator taurine. Repeated cycles of heavy drinking and withdrawal dysregulate the balance between neuronal excitation (e.g., glutamatergic) and inhibition (e.g., GABAergic). Glutamatergic hyperactivity is associated with alcohol craving and the preoccupation-anticipation stage of the addiction cycle (see Figure 55-3). A preponderance of the preclinical literature suggests that the salient action of acamprosate in AUD is restoration of homeostasis in *N*-methyl-D-aspartate-mediated glutamatergic neurotransmission in early abstinence (Littleton 2007). In contrast to disulfiram, which induces aversion through negative physical effects, or naltrexone, which tempers the pleasurable effects of alcohol, acamprosate acts to normalize the dysregulation in neurochemical systems that has been implicated in the biological mechanisms of AUD. Consistent with this hypothesis, a pharmacometabolomics study identified elevated baseline serum glutamate as a biomarker of acamprosate response in 120 alcohol-dependent patients. Baseline serum glutamate levels were found to be significantly higher in responders compared with nonresponders, and serum glutamate levels of responders were normalized after acamprosate treatment, whereas there was no significant change in glutamate in nonresponders (Nam *et al.* 2015). These results suggest that elevated baseline serum glutamate levels may be a potential biomarker associated with positive acamprosate response. Developing and validating such predictors may improve patient treatment matching and optimize treatment efficacy.

Acamprosate requires around a week to reach steady-state levels in the nervous system. The majority of acamprosate clinical trials are 6-12 months in duration (see Table 55-2). A limited number of posttreatment follow-up studies have shown the effects of acamprosate to be sustained for periods up to 1 year after the last dose, consistent with its action in restoring and maintaining homeostasis in brain glutamate activity (Mason and Heyser 2010). Meta-analyses of 27 acamprosate randomized controlled trials involving 7,519 adults with AUD found that the NNT to prevent a return to any drinking with acamprosate was 12 (Jonas *et al.* 2014). These findings corroborate results from a meta-analysis reporting an NNT of 7.5 for attainment of complete abstinence; detoxification and required abstinence (mean = 6.2 +- 5.5 days) prior to acamprosate administration were associated with increased efficacy (Maisel *et al.* 2013).

Similarly, a multicenter trial conducted in the United States found patient choice of abstinence as a treatment goal to be predictive of acamprosate efficacy (Mason *et al.* 2006). Another meta-analysis that obtained individual records from 1,317 women and 4,794 men who participated in 22 acamprosate studies found an incremental gain of 10.4% ($P < 0.001$) in the percentage of abstinent days, an incremental gain of 11.0% ($P < 0.001$) in the percentage of no heavy drinking days, an OR of 1.9 ($P < 0.001$) for rate of complete abstinence, and an OR of 1.9 ($P < 0.001$) for rate of no heavy drinking over the study duration, with no differences in the rate of discontinuation due to adverse events or severity or type of adverse event for patients treated with acamprosate relative to placebo (Mason and Lehert 2012). Acamprosate was also associated with significantly higher rates of treatment completion ($P = 0.004$) and medication compliance ($P < 0.001$) than placebo.

Acamprosate has low bioavailability, which requires that divided doses (two 333-mg tablets) be taken three times daily. It is suggested that patients set reminders on their smartphones, place a 1-week supply of acamprosate in a pill tray (purchased over the counter [OTC]) with the day and time of dose indicated, or use a Bluetooth-enabled smart pill dispenser that sends notifications to avoid missed doses. Acamprosate is excreted primarily by the kidneys. Given the risk of accumulation of acamprosate with prolonged administration of therapeutic doses in patients with renal impairment (Wilde and Wagstaff 1997), the use of acamprosate is contraindicated in patients with severe renal impairment (creatinine clearance < 30 mL/min); a dosage adjustment to one 333-mg tablet administered three times daily is recommended for patients with moderate renal impairment (creatinine clearance 30-50 mL/min; Saivin *et al.* 1998; Wilde and Wagstaff 1997). No dosage adjustment is required for patients with mild renal impairment (creatinine clearance > 50 mL/min). Acamprosate is not metabolized by the liver and can be given safely to patients with liver disease. It is not associated with drug-drug interactions. It does not interact with alcohol (as does disulfiram), nor does it precipitate opioid withdrawal in patients using opioids (as does naltrexone). Acamprosate has also been found to not interact with medications commonly prescribed to individuals with AUD, such as disulfiram, antidepressants, anxiolytics, or hypnotics (Rosenthal *et al.* 2008). Pharmacokinetic studies found that coadministration with naltrexone increased the rate and extent of acamprosate absorption without compromising tolerability (Johnson *et al.* 2003; Mason *et al.* 2002). These results suggest that this combination therapy may improve acamprosate's bioavailability. Diarrhea, typically mild to moderate at the start of treatment, is the side effect most commonly associated with acamprosate (17%) relative to placebo (10%) (Merck Sante 2005). Adverse events of a suicidal nature were infrequent in clinical trials but were more frequent with acamprosate than placebo treatment (1.4% vs. 0.5% in studies of 6 months' duration or less, 2.4% vs. 0.8% in year-long studies). Patients should be monitored for the emergence of symptoms of depression or suicidality. Meta-analyses found acamprosate to be not significantly different from placebo in terms of risk of withdrawal from treatment due to adverse events (Jonas *et al.* 2014; Mason and Lehert 2012).

Summary

In summary, acamprosate, naltrexone, and disulfiram are evidence-based FDA-approved pharmacotherapies for AUD that have been used safely and effectively for

decades. The potential benefits for appropriately selected patients have been found to outweigh the harms, in particular given the risks of continued alcohol misuse (American Psychiatric Association 2017). A comparative summary of treatment parameters for these medications is presented in Table 55-2. Each variable in Table 55-2 is derived from the most comprehensive data available, including meta-analyses, package inserts, and multicenter trials.

APA Practice Guideline Recommendations for Medications Repurposed for Treatment of Alcohol Use Disorder

The underutilization of existing pharmacotherapies points to a need for new medications to safely and effectively treat AUD. Repurposing existing medications with known safety and tolerability profiles that are FDA approved for other indications may help to expeditiously meet this need. Topiramate and gabapentin, two drugs that were originally developed as antiepileptic medications, have shown therapeutic potential for AUD in multiple investigator-initiated trials. The APA practice guideline recommends that topiramate or gabapentin be offered to patients who have a goal of decreasing or quitting drinking, who prefer these medications to the other available options, or who cannot tolerate or have not responded to acamprosate and naltrexone and have no contraindications to the use of these medications (American Psychiatric Association 2017). Co-occurring disorders, concomitant medications, and side-effect profiles are additional factors that may guide the selection of topiramate or gabapentin. Antiepileptic drugs, including gabapentin and topiramate, increase the risk of suicidal thoughts or behavior in about 1 in 500 patients who take these drugs for any indication. An assessment of suicidality at baseline and throughout treatment is therefore warranted. In addition, abrupt withdrawal from these drugs has precipitated seizures and status epilepticus; thus, on-and-off titration is indicated.

Topiramate

Topiramate (Topamax and generic) was approved by the FDA as an oral antiepileptic drug in 1998 and for prophylaxis of migraine in 2004. Topiramate is hypothesized to act in AUD by reducing alcohol's reinforcing effects by facilitating GABAergic function and inhibiting glutamatergic pathways in the corticomesolimbic system (Johnson *et al.* 2007). A meta-analysis of randomized controlled trials of 3 months' duration with dosage titration to a target dosage of 200-300 mg/day found topiramate to be associated with fewer drinking days (WMD, -6.5%), fewer heavy drinking days (WMD, -9%), and fewer drinks per drinking day (WMD -1.0) than placebo (Jonas *et al.* 2014). Of note, patients were typically not required to be abstinent at the start of treatment, although concomitant behavioral therapy was provided that was oriented to working toward abstinence or nonharmful drinking. A pharmacogenetic study found topiramate's effect on heavy drinking to be moderated by rs2832407, a noncoding single nucleotide polymorphism in *GRIK1*, which suggests a role for the kainate receptor in the mechanism of topiramate's effect on heavy drinking (Kranzler *et al.* 2014). If the effect is replicated, this genetic marker may identify patients likely to respond to topiramate.

Topiramate has no contraindications but has a number of warnings and precautions. To mitigate risk, recommended lab tests include baseline and periodic measures of serum bicarbonate to detect treatment-emergent metabolic acidosis, baseline tests of renal function because creatinine clearance greater than 70 mL/min requires a dosage adjustment to half the usual starting and maintenance dosage, and baseline tests of hepatic function because topiramate plasma concentration is increased in hepatic impairment.

Meta-analyses found that patients with AUD who were treated with topiramate had a higher risk of cognitive dysfunction (number needed to harm [NNH] = 12), paresthesias (NNH = 4), and taste abnormalities (NNH = 7) than did patients treated with placebo (Jonas *et al.* 2014). Cognitive dysfunction is an adverse event commonly associated with topiramate, symptoms of which may include confusion; psychomotor slowing; attention, concentration, and memory impairment; and speech or language problems (in particular, word-finding difficulties [Salinsky *et al.* 2005]). Other adverse events involving the CNS include dizziness, somnolence, fatigue, depression, and mood problems. CNS events are often dosage related and more likely to occur with a rapid dosage titration and high initial dosage. Other warnings include risk for acute myopia and secondary angle closure glaucoma, decreased sweating and increased body temperature, suicidal behavior and ideation, kidney stones, hyperammonemia, and encephalopathy. Patients with and without a history of seizure should be gradually withdrawn from topiramate to minimize the potential for seizures. Topiramate interacts pharmacokinetically with some antiepileptic drugs, CNS depressants, oral contraceptives, metformin, lithium, and carbonic anhydrase inhibitors, with significant changes in drug plasma concentrations; refer to the package insert for guidance. Topiramate is Category D in pregnancy. Exposure to topiramate in utero increases the risk of cleft lip and/or palate, in particular if exposure occurs in the first trimester (when many women do not know they are pregnant). Topiramate passes into breast milk.

Gabapentin

Gabapentin (Neurontin and generic) was approved by the FDA as an oral antiepileptic drug in 1993 and as a treatment for postherpetic neuralgia in 2002. A once-daily extended-release formulation (Gralise) and a gabapentin prodrug (Horizant) are FDA approved for postherpetic neuralgia, and

Horizant is approved for restless legs syndrome. All but one trial in AUD were conducted with the original gabapentin formulation.

Gabapentin is an amino acid designed as a structural analogue of GABA and is not a direct GABA agonist (Sills 2006). Gabapentin binds to the alpha-2-delta type 1 subunit of voltage-gated calcium channels (Uchitel *et al.* 2010; Xiao *et al.* 2007). Gabapentin selectively inhibits Ca^{2+} influx through these voltage-operated Ca^{2+} channels (Fink *et al.* 2000), which results in its ability to reduce postsynaptic excitability and decrease the release of excitatory neurotransmitters (Cunningham *et al.* 2004). Possibly via its actions to block excitatory neurotransmission, gabapentin increases the concentration of GABA in the brain (Gotz *et al.* 1993; Taylor *et al.* 1998). In animal models of alcohol dependence, gabapentin decreased amplitudes of GABA receptor-mediated inhibitory postsynaptic currents in the central nucleus of the amygdala and decreased alcohol drinking (Roberto *et al.* 2008). As shown in Figure 55-3, the extended amygdala is the key brain region associated with negative affect in protracted withdrawal.

The potential efficacy of gabapentin as a treatment for AUD was assessed in a human laboratory model of protracted withdrawal. Non-treatment-seeking volunteers with alcohol dependence who were randomly assigned to double-blind treatment with 1,200 mg/day gabapentin showed significantly less craving when exposed to in vivo alcohol cues after 3 days of abstinence and also had improved sleep quality, latency, and efficiency relative to volunteers taking placebo (Mason *et al.* 2009). Support for the safety and efficacy of gabapentin as a treatment for AUD is provided by a number of investigator-initiated single-site treatment studies (Anton *et al.* 2009, 2011, 2020; Brower *et al.* 2008; Chompookham *et al.* 2018; Furieri and Nakamura-Palacios 2007; Karam-Hage and Brower 2000, 2003; Mason *et al.* 2014). Studies have mostly been double-blind, placebo-controlled designs with random assignment and have been conducted across multiple geographic regions, including North and South America and Asia. A systematic review found that studies requiring 3 or more days of abstinence at treatment initiation showed the most robust treatment effects (Mason *et al.* 2018). Conversely, studies that did not require abstinence at treatment initiation or that involved alcohol administration were unlikely to show efficacy for gabapentin for craving and/or drinking outcomes. Studies that evaluated two dosages of gabapentin found greater efficacy for the higher dosage (1,200 mg/day, 1,600 mg/day, or 1,800 mg/day) relative to the lower dosage studied (900 mg/day) (Mason *et al.* 2014; Myrick *et al.* 2009; Salehi *et al.* 2011). A 12-week trial (*N* = 150) of 0 mg/day, 900 mg/day, and 1,800 mg/day gabapentin found significant linear dosage effects on rates of abstinence, rates of no heavy drinking, number of drinks per week, and number of drinking days per week, and on secondary measures of craving, negative affect, and insomnia (Mason *et al.* 2014). The 1,800-mg/day dosage was associated with an NNT of 5 for no heavy drinking and an NNT of 8 for complete abstinence. A multicenter trial of gabapentin enacarbil 1,200 mg/day did not find efficacy for AUD but did include a pharmacokinetic analysis that found higher levels of gabapentin in plasma to be associated with lower alcohol consumption (Falk *et al.* 2019). An independent reanalysis of the clinical data was conducted to identify a profile of likely responders; this subset showed a significantly greater effect of gabapentin enacarbil on the rate of heavy drinking and number of drinks per week relative to placebo (Laska *et al.* 2020).

Studies of FDA-approved indications have often reported a secondary beneficial effect of gabapentin on measures of sleep. Administration of alcohol at bedtime to normally functioning subjects was used to induce sleep disruption in a double-blind, randomized crossover study of gabapentin in a sleep lab setting with polysomnography and subjective measures (Bazil *et al.* 2005). Gabapentin improved sleep by significantly decreasing stage 1 sleep and the number of awakenings and increasing sleep efficiency relative to placebo. Importantly, gabapentin did not differ from placebo on tests of daytime drowsiness or performance. Off-label clinical studies and multiple studies of AUD report beneficial effects of gabapentin on sleep as well as on subsyndromal anxiety and mood symptoms (for a review, see Mason *et al.* 2018). These clinical findings are consistent with basic research suggesting that gabapentin may support recovery by restoring homeostasis in brain stress systems that become dysregulated in the protracted withdrawal/negative affect phase of AUD (Roberto *et al.* 2008). Research suggesting that gabapentin may be most effective in individuals with symptoms of acute alcohol withdrawal was challenged because individuals with clinically significant symptoms of acute alcohol withdrawal were systematically excluded from participation in this research (Anton *et al.* 2020; Kleinman and Ostacher 2020). However, initiating gabapentin dosage titration in conjunction with alcohol detoxification may assist in decreasing withdrawal-related anxiety and insomnia as well as serve as a transition to longer-term relapse prevention treatment during protracted withdrawal (Myrick *et al.* 2009). Gabapentin should not be considered a stand-alone treatment for severe acute alcohol withdrawal because of its ineffectiveness in suppressing seizures related to alcohol withdrawal. The APA practice guideline recommends that gabapentin be used for the treatment of AUD, not alcohol withdrawal.

All gabapentin treatment studies were conducted in patients who concomitantly received behavioral treatment. Systematic reviews and meta-analyses suggest that combining gabapentin with behavioral support provides an incremental advantage in drinking outcomes relative to behavioral support with placebo (Cheng *et al.* 2020; Kranzler *et al.* 2019; Leung *et al.* 2015; Mason *et al.* 2018). Gabapentin may be a useful treatment for patients with AUD and symptoms of sleep disturbance and negative affect, as well as those with chronic pain syndromes, per the FDA-approved pain indication for gabapentin.

There are no contraindications to gabapentin other than known hypersensitivity to the medication. Gabapentin is not metabolized in the liver and can be used safely by patients with liver disease. It is eliminated from systemic circulation by renal excretion as unchanged drug. A baseline test of creatinine clearance is indicated. The dosage should be adjusted for patients with reduced renal function (creatinine clearance < 60 mL/min). Gabapentin ([?] 1,800 mg/day) resulted in no serious safety concerns among the approximately 1,000 outpatients with AUD who participated in studies up to 12 weeks in duration at dosages up to 1,800 mg/day. Adverse events tended to be mild to moderate and tended not to differ from placebo. Common adverse events included headache, insomnia, fatigue, muscle aches, and various gastrointestinal complaints in patients with AUD treated with both gabapentin and placebo (Mason *et al.* 2018). Common side effects with gabapentin enacarbil were fatigue, dizziness, and somnolence (Falk *et al.* 2019). Gabapentin treatment outcomes and adverse effects do not appear to differ between men and women with AUD. On the basis of clinical and postmarketing experience from use for approved pain and epilepsy indications, gabapentin is considered to have a good safety and tolerability profile. The most commonly reported adverse events with gabapentin in comparison with placebo in non-AUD pivotal trials have included dizziness, somnolence, peripheral edema, ataxia, fatigue, and nystagmus. As with any centrally active drug, patients should be advised not to drive motor vehicles or operate heavy machinery until they have ascertained that the drug does not affect their performance. As with other anticonvulsants, monitoring for suicidality and titrating off treatment to reduce seizure risk are indicated.

Reports of abuse of gabapentinoids, such as gabapentin and pregabalin, are increasingly being documented in high-risk populations, notably abusers of opioids and prescription drugs. Alcohol was not found to interact meaningfully with gabapentin in a pharmacokinetic/pharmacodynamic alcohol-gabapentin drug interaction study, nor was gabapentin found to increase BACs or the intoxicating, stimulating, or sedating effects of alcohol (Bisaga and Evans 2006). There was no evidence of tolerance to gabapentin, rebound with titration off the drug, or abuse potential in AUD clinical trials. However, patients who are undergoing opioid withdrawal, those who misuse prescriptions recreationally, and prison populations may be at increased risk of misusing gabapentin, with self-administered doses often far exceeding (by 3-25 times) the therapeutic range (Bastiaens *et al.* 2016; Chiappini and Schifano 2016; Hakkinen *et al.* 2014; Smith *et al.* 2016; Wilens *et al.* 2015). Patients with such risk histories should be monitored for potential gabapentinoid misuse or diversion (e.g., self-escalation of dosage or a "need" for unusually high dosages, repeated requests to replace "lost" medication).

Drugs Approved Outside of the United States for the Treatment of Alcohol Use Disorder

Nalmefene

Nalmefene is an opioid antagonist that is structurally similar to naltrexone but binds more potently to a broader range of opioid receptor subtypes (i.e., the m, d, and k opioid receptors [Michel *et al.* 1985]). Its activity at the k opioid receptor is of interest because activation of this receptor is not associated with alcohol's rewarding effects, as is the case with the m opioid receptor, but instead is linked to increases in anxiety and dysphoria. Consequently, by blocking both the rewarding effects of alcohol and also some of alcohol's anxiogenic and dysphoric effects, nalmefene functions like an opioid partial agonist. Two seminal 12-week double-blind, placebo-controlled clinical trials demonstrating the therapeutic potential of nalmefene (dosages of 10 mg/day, 20 mg/day, 40 mg/day, or 80 mg/day) for the treatment of AUD were conducted in the United States (Mason *et al.* 1994, 1999). Nalmefene at dosages greater than or equal to 20 mg/day was found to significantly reduce the risk of heavy drinking relative to placebo in outpatients with alcohol dependence, with a rapid onset of effects, which were evident at the first weekly clinic visit.

The European Medicines Agency approved nalmefene (trade name Selincro) in 2013 to help reduce alcohol consumption in adults with alcohol dependence who have a high drinking risk level according to World Health Organization (WHO) criteria (men > 60 g/day and women > 40 g/day) that is sustained for 2 weeks after initial assessment, with nalmefene to be taken 2 hours prior to an anticipated heavy drinking situation. The European Medicines Agency stipulated that nalmefene be used in conjunction with counseling and only by individuals who do not have symptoms of physical withdrawal and do not require detoxification. The agency based its approval on data from two 6-month multicenter trials spanning 11 European countries and involving 1,322 men and women with alcohol dependence. Nalmefene was significantly more effective than placebo in reducing the number of heavy drinking days and daily alcohol consumption (Gual *et al.* 2013; Mann *et al.* 2013; van den Brink *et al.* 2014). In addition, a two-level reduction in

WHO drinking risk levels was examined for treatment effects. These risk levels--very high, high, moderate, and low--are defined on the basis of estimated mean daily ethanol consumption in grams and associated harms (World Health Organization 2000). Secondary analyses found that significantly more nalmefene-treated patients had a two-category downward shift in WHO drinking risk levels relative to those treated with placebo and showed associated

improvements in LFT values and in both clinician ratings and self-ratings of mental and physical health (Aubin *et al.* 2015). Analyses of additional datasets have shown that one-and two-level reductions in WHO drinking risk levels are stable for up to 3 years after treatment and are associated with significantly better mental and physical health and quality of life (Witkiewitz *et al.* 2020).

Thus, both the FDA-approved heavy drinking outcomes and the WHO risk level-based outcomes have broad clinical relevance for individuals who recognize that they have a problem with alcohol but are not ready to quit drinking entirely. An indirect meta-analysis compared four placebo-controlled trials of nalmefene and 13 naltrexone trials and found a significant advantage for nalmefene relative to naltrexone in terms of drinking quantity and frequency (Soyka *et al.* 2016). Findings for the efficacy of nalmefene 20 mg/day taken as needed in adults with alcohol dependence at high drinking risk or greater have been replicated in Japan (Higuchi *et al.* 2020; Miyata *et al.* 2019); nalmefene is now approved for use in reduction of alcohol consumption in many countries worldwide but to our knowledge has not been submitted for FDA approval.

Baclofen

Baclofen (Lioresal and generic) is an oral selective $GABA_B$ receptor agonist (for a review, see de Beaurepaire *et al.* 2019). Baclofen was approved by the FDA in 1977 for the treatment of muscle spasticity secondary to neurological conditions. In 2018 the French Medicines Agency granted marketing authorization for baclofen (at a maximum dosage of 80 mg/day) to support drinking reduction in alcohol dependence after other approved drugs have failed. It has been hypothesized that the pharmacotherapeutic action of baclofen in AUD may be to suppress the ventral tegmental area dopamine system and blunt reinforcement. The approval in France was driven by reports of widespread off-label use of baclofen and not based on scientific evidence. Initial reports were positive in 39 male participants with AUD, showing that treatment with baclofen 30 mg/day increased the percentage of individuals who achieved and maintained abstinence and decreased the number of drinks per drinking day and anxiety levels (Addolorato *et al.* 2002). However, these results have not been consistently observed in subsequent studies or in treatment settings using dosages up to 300 mg/day (Minozzi *et al.* 2018). In addition, the use of baclofen remains controversial, in part because of uncertainty regarding dosing and efficacy along with concerns about safety. A pharmacoepidemiological cohort study found a dose-dependent increased mortality risk with baclofen in alcohol dependence (Chaignot *et al.* 2018). Individuals should be informed to avoid drinking while taking the drug, as the sedative properties of both drugs may potentiate each other. Individuals should be advised not to drive motor vehicles or operate heavy machinery until they have ascertained that the drug does not affect their performance. Individuals should also be advised of the risk of overdose. Side effects range from moderate to more dangerous and include seizures, respiratory depression with sleep apnea and potentially coma (in case of intoxication), severe mood disorders (mania or depression, with the risk of suicide), exacerbation of psychosis, and mental confusion/delirium. Baclofen is mostly (~ 80%) eliminated from systemic circulation by renal excretion as unchanged drug. Therefore, baseline and repeated tests of renal function are recommended given that renal problems can lead to an accumulation of baclofen that may result in mental confusion.

Baclofen treatment should start and end gradually, as there is a withdrawal syndrome associated with abrupt cessation of treatment; withdrawal symptoms may include confusion, agitation, seizures, and delirium and may be confused with alcohol withdrawal (Rolland *et al.* 2014). A consensus statement by a panel of international experts on the use of baclofen for AUD concluded that more research is needed to clarify the potential efficacy and safety of baclofen in treating AUD (Agabio *et al.* 2018).

Initiation and Monitoring of Pharmacological Treatment

A baseline of alcohol use should be established, preferably using quantitative self-report and biochemical measures, against which treatment effects can be tracked. Likewise, harmful effects of alcohol on the patient's health, functioning, and legal status should be documented. The clinician should rule out concomitant disorders such as nicotine and other substance use disorders (SUDs), which may influence AUD outcome if left untreated. Risk of suicide may be elevated in patients with AUD; although rare, suicide has occurred in patients taking pharmacotherapies for AUD. Therefore, screening for suicidality at baseline and periodically thereafter may identify an increased suicide risk that requires further intervention. An integrated treatment plan specific to the patient should be developed to address both AUD and clinically significant concurrent conditions.

Patient safety is optimized by adhering to the recommended dosage and noting the medical contraindications and cautions on the product label. A physical exam and laboratory testing are recommended before treatment is initiated and may help with subsequent monitoring of response to treatment (Center for Substance Abuse Treatment 2009). Useful tests include an alcohol breathalyzer reading, a UDS, LFTs (ALT, AST, GGT), bilirubin, compete blood count, testing for vitamin deficiencies, renal function tests (a standard panel for urea [blood urea nitrogen], electrolytes, and serum creatinine), and a pregnancy test for women of childbearing potential. Obtaining a baseline UDS, LFTs, and measures of creatinine clearance may guide medication selection. A UDS may provide information about otherwise undisclosed drug use, including opioid use, which is exclusionary for naltrexone treatment of AUD. Baseline LFTs may detect clinically significant hepatic impairment that would rule out treatment with disulfiram and naltrexone. Similarly, a baseline test of creatinine clearance may identify severe impairment (< 30 mL/min) in creatinine clearance that would contraindicate the choice of acamprosate. It is recommended that individuals taking disulfiram have repeat bilirubin and LFTs at 2 weeks, then monthly for 6 months and every 3 months thereafter. Carrying a wallet card is advisable to notify emergency personnel that the patient is taking naltrexone (e.g., should anesthesia or pain management be required) or disulfiram (e.g., in case an alcohol-disulfiram interaction is precipitated).

The patient should be informed about what to expect from taking a medication: how it may help AUD and potential risks and side effects. A patient information sheet providing this information in writing can be taken home by the patient for future reference.

A phone call can be scheduled with the patient for a few days after a prescription has been provided to facilitate successful initiation of medication, address any concerns, and assess medication adherence and side effects. Given the common side effects of drowsiness and dizziness, patients should be advised at baseline to avoid driving a car or operating heavy machinery until they are reasonably certain that the drug does not affect their ability to engage in such activities. OTC remedies (e.g., Pepto-Bismol) may be used, if needed, for diarrhea and nausea. Patients should be given a phone number to call and instructed to inform their treatment provider immediately if suicidal ideation or depression develops or if symptoms of acute hepatitis or liver failure emerge (in the case of naltrexone and disulfiram).

Integration of Pharmacotherapy With Nonpharmacological Treatments

Nonpharmacological approaches to treating AUD have long been the standard in the field, whether in a clinical setting or in a self-help group. Essentially all of the clinical trials covered in this chapter either evaluated a medication given in addition to the routine AUD treatment patients would ordinarily receive in that setting or used a manual-guided form of behavioral therapy--for example, AlcoholFree (Mason and Goodman 2005), motivational enhancement therapy (MET; Miller *et al.* 1995), cognitive-behavioral coping skills therapy (Kadden *et al.* 1995), or 12-step facilitation therapy (Nowinsky *et al.* 1992).

The goal of most pharmacotherapy trials was to demonstrate that behavioral therapy combined with medication had a higher rate of treatment response than behavioral therapy combined with placebo. Meta-analyses have shown that on average pharmacotherapies for AUD have a small but significant treatment effect size relative to placebo in patients provided with concomitant behavioral therapy (Jonas *et al.* 2014). Efforts to identify phenotypes, genotypes, and biomarkers predictive of response (described previously) are aimed at guiding the selection of a pharmacotherapy to optimize the likelihood of response for a given patient. However, it is common to associate pill and cure, and medication should be presented as one tool in a toolkit of evidence-based treatments for AUD. Yet some members of self-help groups have criticized members who take AUD medication as not having a true, drug-free recovery. None of the pharmacotherapies for AUD are alcohol-substituting drugs in the way that methadone is for heroin, and this criticism reflects a lack of understanding of drug mechanisms. Physician members of Alcoholics Anonymous (AA) composed a pamphlet that patients can access online advising that AA members "not play doctor" and offering useful guidelines for discriminating appropriate from risky use of medications in patients with AUD and other drug use disorders (Alcoholics Anonymous 2018).

Medications can help restore normal brain functioning, reduce relapse risk, and decrease symptoms of protracted withdrawal (e.g., craving), thereby facilitating the patient's engagement in behavioral treatment. Behavioral therapies in turn enhance the pharmacotherapy response by modifying the patient's attitudes and behaviors related to alcohol, increasing healthy life skills, and helping them stay engaged in treatment.

The National Institute on Alcohol Abuse and Alcoholism (NIAAA) Alcohol Treatment Navigator (https://alcoholtreatment.niaaa.nih.gov) is a website designed to assist in locating clinicians who provide evidence-based behavioral and/or pharmacological treatments for AUD (National Institute on Alcohol Abuse and Alcoholism 2017). Integrating pharmacological and behavioral treatments for AUD increases the likelihood of patients meeting their goals for treatment.

Treatment Response and Recovery

Assessing Treatment Response

A self-report of the number of standard drinks consumed daily combined with a biochemical measure of alcohol intake is used for assessing AUD pharmacotherapy response. Urine dipstick measures of alcohol glucuronide and handheld analyzers of alcohol in expired breath can provide a direct indication of alcohol use near the time the sample is collected. However, given the fast metabolism of alcohol, its use cannot be detected in breath, urine, or plasma over an extended time interval between clinic visits. Indirect biomarkers of alcohol use between clinic visits (e.g., GGT, mean corpuscular volume, and carbohydrate-deficient transferrin) have limitations with regard to sensitivity and/or specificity that can contribute to over-or underestimation of alcohol use. Direct and indirect biomarkers of alcohol use are often used in combination to support the validity of self-reported data.

The gold standard for self-reporting of alcohol use is a standardized interview in a calendar format, typically a variation of the Timeline Followback Interview (Sobell and Sobell 1992), which uses prompts such as weekend versus weekdays, paydays, or holidays to assess the quantity and frequency of alcohol consumption between clinic visits using a *standard* drink metric (see Figure 55-2). One standard drink is defined as containing about 14 g (0.6 fluid ounces) of pure alcohol, which is found in 12 ounces of regular beer, 5 ounces of wine, and 1.5 ounces of distilled spirits. Computerized administration is also available to encourage accurate reporting by patients. As an alternative, patients may record their alcohol use on a smartphone app (e.g., AlcooQuizz [Bertholet *et al.* 2019[]) or keep a daily diary of dose(s) taken, abstinence or drinking, and the circumstances associated with a drinking episode. Reviewing these data with the patient at clinic visits may facilitate treatment outcomes by monitoring their progress and identifying high-risk occasions for relapse and strategies for coping. With the patient's permission, periodic interviews with their significant other may be used to validate their self-report of alcohol use, medication adherence, adverse drug effects, and general functioning.

Remission and Recovery

DSM-5 includes specifiers of remission for individuals whose symptoms previously met criteria for AUD but who have experienced none of the symptoms (except craving) for at least 3 and less than 12 months (for early remission) or for 12 months or longer (for sustained remission). NIAAA has recently proposed a new definition of recovery that expands on DSM-5 remission criteria to also include cessation of heavy drinking as a non-abstinence recovery outcome (National Institute on Alcohol Abuse and Alcoholism 2022b). Cessation of heavy drinking is associated with improved social functioning and quality of life, which in turn enhances and sustains remission (Hagman *et al.* 2022). Thus, recovery is conceptualized clinically both as an outcome and as an ongoing process.

Medication Management Issues

Medication Adherence

Medication nonadherence is a common factor influencing pharmacotherapy outcomes across many conditions, including AUD. When it occurs, factors such as adverse drug events or problems managing the dosing schedule should be assessed. Standard measures to ensure adherence may include instructing patients to set reminders on their smartphones and to package their medication in OTC weekly pill trays with the day and time of day indicated for each dose. Identify frequently missed doses by asking patients to bring their pill tray and unused medication at every visit, and link commonly missed doses with an activity of daily living such as eating meals or brushing teeth as a reminder to then take their medication. As an alternative, a Bluetooth-enabled medication management system can alert patients to take scheduled doses and automatically record when doses were taken or missed; this information can be shared electronically with their treatment provider. Patients can reaffirm a commitment to their recovery with every dose taken.

Treatment Duration

There is little scientific evidence to guide the optimal duration of pharmacological treatment of AUD. A patient's history of relapses and the potential consequences of a relapse, the severity of AUD at baseline, and the patient's clinical response and side effects may be determining factors. These factors should be probed if a patient indicates a wish to discontinue treatment before remission and a stable recovery has been established.

Nonresponse or Partial Response to Treatment

An option for nonresponse to treatment may be to switch to an alternative AUD medication, barring any medical contraindications. Partial response to an adequate trial at the recommended dosage of a medication is a challenge. If a relapse to heavy drinking occurs among patients taking acamprosate or naltrexone, they should be instructed to continue taking the medication as prescribed. Relapses may be briefer in duration and less severe if these medications are continued, and neither medication interacts with alcohol. Alternatively, a patient may have reduced his or her drinking by half from baseline but may continue to have episodes of heavy drinking. One may consider the use of combined treatments on a case-by-case basis. There are data that lend support to the safety of acamprosate combined with naltrexone or disulfiram (Besson *et al.* 1998; Johnson *et al.* 2003; Jonas *et al.* 2014; Mason *et al.* 2002), but efficacy data are insufficient to support a general recommendation for combined use as a first-line approach to treating AUD (American Psychiatric Association 2017). Given a potentially increased risk of hepatotoxicity when naltrexone and disulfiram are used in combination, this combination is rarely considered.

Special Populations

Women

A national 2021 survey (Substance Abuse and Mental Health Services Administration 2021a) found that 13 million American women (9.1%) had symptoms that met criteria for AUD in the past year. A review of survey data showed that alcohol use in women is increasing to the point that male and female drinking patterns are now converging (Substance Abuse and Mental Health Services Administration 2021a; White *et al.* 2015). However, with comparable alcohol intake, women are more likely than men to experience a variety of alcohol-related harms, including liver damage, cardiac disease, cognitive deficits, breast cancer, and other health problems, in part because of gender differences in total body water and alcohol metabolism (Bradley *et al.* 1998; Greenfield 2002). Binge drinking among women (defined as consuming four or more drinks in a row) may confer increased risk of accident, rape, assault, and unprotected sex (Wechsler *et al.* 1995). Among individuals with AUD, depression and anxiety disorders, with the associated risk of suicidality, are also more prevalent among women than among men (Conway *et al.* 2006). Alcohol use by pregnant women can have profound effects on the developing fetus. These effects can lead to a range of impairments, including fetal alcohol spectrum disorders, which are characterized by intellectual disability, speech and language delays, social skills deficits, and sometimes facial deformities. Despite the broader range of increased harms of alcohol misuse in women relative to men, women are less likely than men to receive AUD treatment (Gilbert *et al.* 2019). Given the significant disease burden of AUD in women, early intervention and effective treatment options are clearly needed.

A sex-specific meta-analysis of individual records obtained from 1,317 women and 4,794 men who participated in 22 acamprosate clinical trials found a significantly greater effect of acamprosate relative to placebo on rates of abstinence and no heavy drinking, and effect sizes did not differ between men and women (Mason and Lehert 2012). Despite a history of significantly more anxiety, depression, suicide attempts, drug abuse, interpersonal loss, and greater liver impairment at baseline than men, women responded comparably well to AUD treatment. The side-effect and tolerability profile of acamprosate was comparable to that of placebo in terms of number, type, and severity of adverse events and did not differ between women and men. Acamprosate was also associated with significantly higher rates of treatment completion and medication compliance than placebo among both women and men. Potential differences in drug metabolism due to sex hormones or race (e.g., the flushing response to alcohol), and consequent effects on drug efficacy or safety, point to the need for adequate diversity, equity, and inclusion in AUD clinical trials.

Pregnant Women

Disulfiram, naltrexone, acamprosate, and gabapentin are Pregnancy Category C; topiramate is Pregnancy Category D. There are no adequate or well-controlled studies of AUD medications in pregnant women. It is generally recommended that AUD medications not be used during pregnancy, unless acute alcohol withdrawal is being treated with benzodiazepines (American Psychiatric Association 2017).

Nursing Mothers

Topiramate and gabapentin are secreted in human milk; it is not known whether acamprosate, disulfiram, and naltrexone are excreted in human milk. Caution should be used when administering topiramate, gabapentin, acamprosate, or naltrexone to a nursing woman, and disulfiram should be avoided (Alkermes 2010; Duramed Pharmaceuticals 2013; Merck Sante 2005; Teva Pharmaceuticals USA 2015).

Children

Drinking is illegal before the age of 21 years in the United States, and alcohol misuse rather than AUD of moderate or greater severity is more characteristic of this age group. Nevertheless, it is never too early (or too late) to treat AUD. Small (N = 26) double-blind, placebo-controlled studies in adolescents have reported good tolerability and higher rates of abstinence with acamprosate and disulfiram relative to placebo (Niederhofer and Staffen 2003a, 2003b).

Adults Ages 65 and Older

Patients older than 65 years have been included in some clinical trials of disulfiram (De Sousa and Jagtap 2009), naltrexone (Garbutt *et al.* 2005), and acamprosate (Mason *et al.* 2006), but not in sufficient numbers to analyze differences in safety and efficacy from younger patients. Older patients may be at increased risk for hepatic, renal, or cardiac problems; other disorders; or use of concomitant medications that may affect the choice of pharmacotherapy for AUD and indicate a need for close monitoring.

Individuals With Co-Occurring Alcohol Use Disorder and Another Psychiatric Disorder

AUD is the second most commonly identified mental disorder among suicide completers worldwide; the most common is mood disorder (Cavanagh *et al.* 2003). When AUD and mental disorders co-occur, suicide risk may increase--for example, depression may promote increased alcohol intake; alcohol may promote dysphoria, hopelessness, impaired problem solving, and aggression. Concurrent treatment of co-occurring disorders associated with suicide risk, such as depression and AUD, is indicated to reduce the risk of suicide. Meta-analyses suggest that women with AUD have about a sixteen-fold increased risk for suicide compared with women in the general population, whereas men with AUD have about a ninefold increased risk of suicide compared with men in the general population (Kaplan *et al.* 2013). Acute alcohol use can be a powerful precipitant for suicidal behavior, and suicide risk increases with the amount of alcohol consumed (Conner and Bagge 2019). For example, 24% of male suicide decedents and 17% of female suicide decedents were found to have postmortem BAC levels exceeding 0.08g/dL (Kaplan *et al.* 2013). The marked association between AUD and suicide risk underscores the necessity of diagnosing and effectively treating AUD.

Assessment and Treatment of Psychiatric Disorders in Patients With Alcohol Use Disorder

An accurate psychiatric diagnosis cannot be made when a patient is drinking or withdrawing from alcohol; alcohol may reduce some psychiatric symptoms, and conversely symptoms of anxiety and depression may be mistaken for withdrawal instead of an underlying disorder that requires independent treatment. Symptoms of psychiatric disorders should lead to further integrated assessment and treatment planning, with both AUD and co-occurring disorders considered primary disorders. Patients with AUD and concurrent disorders may benefit from a chronic care management approach that includes evidence-based behavioral and pharmacological treatments; social support services; and clinical monitoring of adverse events, medication adherence, and symptoms of relapse. It is important to work collaboratively with the patient and involved significant others, communicate the risks and benefits of each treatment option relative to the patient's recovery goals, and ensure that the patient comprehends this information. The selection of psychiatric medications for patients with AUD requires consideration of abuse potential and potential interactions with other medications, tobacco, illicit drugs, and alcohol, which may affect drug metabolism and safety and warrant enhanced monitoring.

Effects of Acamprosate or Gabapentin on Other Psychotropic Medications and on Sleep

Acamprosate and gabapentin are not metabolized in the liver, and thus drug-drug interactions via cytochrome P450 inhibition are unlikely. The pharmacokinetics of acamprosate are not altered by coadministration with an anxiolytic, an antidepressant medication, or alcohol (Rosenthal *et al.* 2008), which suggests that acamprosate can be used safely by patients with AUD who are receiving concomitant medications for concurrent psychiatric disorders.

Several studies have suggested that acamprosate and gabapentin may help normalize the underlying neurobiological mechanisms of alcohol-related disturbances in sleep (Bazil *et al.* 2005; Staner *et al.* 2006). Sleep disturbances are a challenge often faced by recently detoxified patients. A polysomnography study showed that acamprosate improved sleep continuity, restored N3 (slow-wave) sleep, and increased rapid eye movement sleep latency, all of which are classically described as important determinants of relapses (Brower *et al.* 2001). Another polysomnography study showed that gabapentin decreased N1 sleep and arousals while increasing N3 sleep and sleep efficiency relative to placebo in subjects pretreated with alcohol (Bazil *et al.* 2005). Subjective sleep data obtained from randomized controlled trials lend clinical support to these polysomnography findings (Mason *et al.* 2018; Perney *et al.* 2012, 2015), and a beneficial effect of acamprosate and gabapentin on sleep may be particularly germane to co-occurring disorders in which sleep disruption is a factor (e.g., depression, anxiety, posttraumatic stress disorder).

Use of Psychotropic Medications in Individuals With Comorbid Alcohol Use Disorder

Practice guidelines recommend that antidepressant medication and benzodiazepines not be used for the treatment of AUD unless there is a concurrent disorder for which these are indicated treatments or unless benzodiazepines are used to treat acute alcohol withdrawal (American Psychiatric Association 2017). Patients with AUD and concurrent major depressive disorder have been found to respond to a range of antidepressant medications (Mason *et al.* 1996; McGrath *et al.* 1996; Pettinati *et al.* 2010; Roy-Byrne *et al.* 2000). Conversely, the use of antidepressant medication to reduce drinking relapse is generally not supported in patients with AUD who are not depressed (Cornelius et al. 2009; de Bejczy and Soderpalm 2015; Friedmann *et al.* 2008; Gorelick and Paredes 1992; Kabel and Petty 1996; Mason *et al.* 1996; Naranjo *et al.* 1990).

Similarly, the use of antipsychotics to reduce the risk of drinking relapse is not supported as a first-line treatment for AUD but may be particularly useful for patients with AUD who have a concurrent disorder for which the drugs are indicated (Anton *et al.* 2008a; Bender *et al.* 2007; Brunette *et al.* 2020; Green *et al.* 2015; Mohamed *et al.* 2015). Bipolar disorder with concurrent AUD can be effectively treated with mood-stabilizing medications (e.g., lithium, quetiapine, valproate), and benefit is also shown for drinking outcomes (Brown *et al.* 2008; Salloum *et al.* 2005). The use of mood-stabilizing medications to reduce the risk of drinking relapse is not effective in patients with AUD who do not have concurrent bipolar disorder (Brown *et al.* 2008, 2014; Fawcett *et al.* 2000; Litten *et al.* 2012).

Anxiety disorders with concurrent AUD respond to some antianxiety medications, such as sertraline (Brady *et al.* 1995) and paroxetine (Book *et al.* 2008; Thomas *et al.* 2008), but not to others, such as venlafaxine (Ciraulo *et al.* 2013). The use of an antianxiety medication to reduce the risk of drinking relapse in patients with AUD who do not have anxiety disorders was not found to be effective in a double-blind, placebo-controlled trial of buspirone (Fawcett *et al.* 2000).

Individuals With Co-Occurring Alcohol Use Disorder and Another Substance Use Disorder

Concurrent Alcohol Use Disorder and Opioid Use Disorder

Naltrexone (oral and injectable) is FDA approved both for the treatment of AUD and for the prevention of relapse in patients with opioid use disorder (OUD) following opioid detoxification. Patients with AUD and concurrent OUD who wish to remain opioid free and to cut down on or quit drinking can receive this single treatment for both disorders in conjunction with a comprehensive management program that includes psychosocial support. Naltrexone is an opioid antagonist and will induce withdrawal in patients who use opioids; therefore, patients must not be using prescribed or illicit opiates when starting naltrexone treatment. Patients receiving Vivitrol must be opioid free for 7-10 days before treatment. It is vital for patients to comprehend that attempting to overcome the blockade produced by naltrexone by taking opioids is very dangerous and may lead to a fatal overdose. Similarly, the use of lower dosages of opioids after Vivitrol is discontinued, at the end of a Vivitrol dosing interval, or after missing a Vivitrol dose could result in life-threatening opioid intoxication (e.g., respiratory arrest and circulatory collapse). Acamprosate is not a treatment for OUD but, unlike naltrexone, may be used safely by patients with concurrent AUD and OUD who choose opioid substitution therapy with methadone or buprenorphine.

Concurrent Alcohol Use Disorder and Nicotine Use Disorder

Varenicline (Chantix) is a partial a4b2 nicotinic acetylcholine receptor agonist that was approved by the FDA as a treatment for smoking cessation in 2006. A number of double-blind, placebo-controlled clinical trials have reported a reduction in alcohol consumption in heavy-drinking smokers treated with varenicline 2 mg/day (Bold *et al.* 2019; Hurt *et al.* 2018; Mitchell *et al.* 2012; O'Malley *et al.* 2018). Importantly, varenicline showed positive effects for the treatment of AUD in a multicenter double-blind,

placebo-controlled clinical trial, in which it lowered the weekly percentage of heavy-drinking days, drinks per drinking day, and alcohol craving compared with placebo (Litten *et al.* 2013). Effects on drinking occurred in both nonsmokers and smokers, which suggests a direct effect on AUD; thus, varenicline is an appealing potential choice for patients seeking treatment for concurrent AUD and smoking cessation. The finding that varenicline decreases alcohol consumption in AUD was replicated in secondary analyses of a Swedish multicenter clinical trial (de Bejczy *et al.* 2015). Of note, a recent double-blind trial that compared combination treatment with varenicline and naltrexone versus varenicline monotherapy in heavy-drinking smokers found significantly greater smoking abstinence with varenicline monotherapy than with the varenicline-naltrexone combination (Ray *et al.* 2021).

Novel Medications Focused on Negative Emotional States in Alcohol Use Disorder

Much of the previous work on medications for AUD was focused on blocking the rewarding effects of drugs in the binge/intoxication stage of the AUD cycle, but identifying a clear role for the motivational signs of withdrawal, as reflected by negative emotional states in the withdrawal/negative affect stage, represents a compelling rationale for focusing on neurobiological targets in this domain.

Some of these potential neurobiological targets have advanced to clinical testing. For example, mifepristone, which acts as a glucocorticoid receptor antagonist, was found to decrease craving and drinking in recently abstinent participants with AUD in a human laboratory model of protracted withdrawal (Vendruscolo *et al.* 2015) and is now under study in a randomized controlled trial. Glucocorticoid receptor signaling in the hypothalamic-pituitary-adrenal axis and extrahypothalamic system may be a potential target for drug development because of a putative dual role (i.e., to normalize reward function and desensitize stress systems).

Vasopressin is a pro-stress, dysphoria-inducing brain neurotransmitter system that converges on the extended amygdala and contributes to negative emotional states associated with protracted withdrawal (Koob 2008). An investigational vasopressin V_{1b} receptor antagonist, ABT-436, was found to increase the rate of abstinence in a multicenter trial of AUD. Furthermore, participants who reported high levels of stress responded better, as evidenced by decreases in both the frequency of drinking and the number of heavy drinking days (Ryan *et al.* 2017).

These trials, combined with others involving gabapentin, lend support to the hypothesis that desensitization of brain stress systems mediates the negative emotional states in protracted withdrawal and offer a valid pharmacological target for treatment of AUD. A complementary pharmacological approach would be to activate anti-stress buffering systems in the brain as a strategy for restoring homeostasis in protracted withdrawal (Koob 2008).

Oxytocin, a neuropeptide that is emerging as a stress buffer, is currently under clinical investigation for the treatment of AUD and withdrawal. Preliminary work showed that intranasal oxytocin was superior to placebo at reducing symptoms of relatively mild alcohol withdrawal (Pedersen *et al.* 2013) and had a dual effect on alcohol craving in a human lab study; more socially anxious subjects who abused alcohol showed decreased

craving, and less socially anxious subjects showed increased craving, with oxytocin relative to placebo (Mitchell *et al.* 2016).

The recent surge in understanding of the neurocircuitry and neuropharmacological mechanisms involved in withdrawal/negative affect and relapse in AUD has provided abundant targets for the development of future medications for treating AUD, as was shown in Figure 55-3. Both repurposed drugs, such as gabapentin, varenicline, and mifepristone, and new molecular entities, such as the vasopressin V_{1b} receptor antagonist, which are all selective for these targets, are showing promise as emerging new treatments for AUD.

Evolving Treatments for Alcohol Use Disorder

Transcranial Magnetic Stimulation

Background and History

Transcranial magnetic stimulation (TMS) is based on the principle of electromagnetic induction developed by the renowned English scientist Michael Faraday during the first half of the nineteenth century (Maxwell 1881). The principle of TMS is rooted in the observation that a brief increase in the flow of an electric current through a coil (a wire in the shape of a spiral that conducts electricity) produces a transient magnetic field. The magnetic stimulators used in TMS work by inducing short electric currents that produce such magnetic fields. In TMS therapy, these magnetic fields are allowed to pass freely into the skull. Because the neurons underneath function like electrical conductors, the propagation of magnetic fields in neurons causes the electric current to flow, exciting or inhibiting neural activity.

Electricity and magnetism are two intertwined and very powerful forces in the universe. There is no magnetism without electricity, and there is no electricity without magnetism. Magnetism is one of the four fundamental forces in nature. Our planet's magnetic field protects the earth by deflecting solar winds. In medicine, the healing properties of magnets were recognized in Ancient Egypt as early as 3200 b.c. Much later, in the 17th century, the English physician William Gilbert allegedly used magnets to relieve the arthritis of Queen Elizabeth I. Today powerful magnets are harnessed to acquire very detailed images of our bodies and our brains with a technology called MRI.

Over the past few centuries, numerous scientists from all over the world have contributed to the development of the science behind the current applications of TMS, from Luigi Galvani (1737-1798), one of the founders of modern electrophysiology, in the eighteenth century to Anthony Barker, who in 1985 developed the prototypes of the so-called Sheffield magnet, which is considered the first TMS device, in the twentieth century (Horvath *et al.* 2011). TMS uses pulsed magnetic fields that are concentrated in an area the size of a small coin. These pulses are generated by a magnetic coil placed on the scalp, allowing precise, noninvasive application over the head. By applying repeated stimulation pulses, repetitive TMS can gradually increase or decrease the activity of specific regions of the brain, such as the dorsolateral prefrontal cortex (dlPFC). The dlPFC plays an important role in AUD and other addictions because this region functions as a neural hub, connecting key brain areas involved in motivation, decision-making, and the ventral tegmental area/dopamine reward system. When the magnetic field delivered by a medical TMS device reaches the cortex, neurons react by generating action potentials, thereby modulating neuronal activity not only within the target region (e.g., the dlPFC) but also in downstream regions to which the target area is connected.

Transcranial Magnetic Stimulation as a Novel Therapy for Alcohol Use Disorder

AUD is a major public health problem around the world. Although effective medications and psychological interventions exist for the treatment of AUD and can reduce harmful alcohol consumption, even with treatment many people with AUD continue to experience challenges with controlling alcohol craving and remain vulnerable to relapse.

As in other addictions and SUDs, many areas of the limbic system, and specifically the frontal cortical regions, are involved in the expression of pathological behaviors associated with AUD, both in animal models and in humans (Rudebeck and Izquierdo 2022). Meta-analyses have revealed significant bilateral gray matter reductions in medial cortical regions across the cingulate and superior frontal gyri, the precuneus, and insular cortices as well as the thalamus, amygdala, and cerebellum in patients with AUD (Spindler *et al.* 2021). These gray matter reductions correspond to behavioral changes, including compromised cognition, emotion processing, and somatosensory and motor functioning, following long-term alcohol misuse (Spindler *et al.* 2021).

Evidence of the ability of TMS to significantly reduce craving and relapse to AUD and other SUDs, in particular cocaine use disorder, has been accumulating for several years (Lolli *et al.* 2021; Madeo *et al.* 2020; Terraneo *et al.* 2016). With respect to AUD, repetitive TMS applied to the right dlPFC suppressed alcohol craving following recent detox (Belgers *et al.* 2022). Similarly, deep TMS reduced craving and the proportion of heavy drinking days compared with sham TMS in people with AUD (Harel *et al.* 2021). Active deep TMS was also linked to decreased functional connectivity among the anterior cingulate cortex, caudate nucleus, and medial prefrontal cortex in people with AUD (Harel *et al.* 2021). On the basis of these and other studies, in 2021 a TMS device received *conformite europeenne* approval in the European Union for the treatment of addiction (Cision PR Newswire 2021).

Interestingly, a significant percentage of patients treated for cocaine use disorder also experience co-occurring AUD. In some reports, up to 85% of people with cocaine use disorder also have symptoms that meet criteria for lifetime AUD (Regier *et al.* 1990). In our experience, the majority of patients initially receiving TMS therapy for cocaine use also report a reduction in alcohol craving and relapse. Going forward, applications of TMS therapy for polysubstance use must be explored.

Taken together, these data suggest that TMS may be a new approach to helping patients with AUD by reducing craving and heavy drinking and mitigating relapse. Given the need for additional effective therapies for AUD and the precedent set in Europe, TMS may move forward for approval for this indication in the United States, as it has for treatment-resistant depression. In addition, with its mild side-effect profile, TMS may be a promising treatment for pregnant women with AUD (Martinez-Gras *et al.* 2021; Pridmore *et al.* 2021).

Ketamine

The history of ketamine begins in the 1950s in the United States. Today this very interesting molecule is gaining increasing attention thanks to its varied potential therapeutic applications. Ketamine was originally discovered in Detroit, Michigan, where scientists at Parke-Davis were focusing their efforts on a quest for the ideal anesthetic agent, which, aside from being a safe anesthetic, would also have the ability to produce analgesia. The discovery of ketamine dates to 1962, when it was originally called CI-581 (2-[O-chloro-phenyl]-2-methyl-amino cyclohexanone). The name *ketamine* derives from the words *ketone* and *amine*, based on its molecular structure. The first human administration of ketamine was in 1964, only 2 years after its discovery, to volunteer subjects in prisons (reviewed in Mion 2017). In the 1970s, low doses of ketamine were found to exert analgesic properties (Sadove *et al.* 1971). The anesthetic and analgesic properties of ketamine, together with its anti-inflammatory effects, led to its use on patients in burn centers. However, when ketamine was used as an anesthetic during the Vietnam War, its psychedelic effects began to raise concerns. Ketamine misuse became prevalent during the Vietnam War and began to occur in the United States (Jansen 2000).

Much later, ketamine was found to have unexpected psychiatric applications. In 2000, Berman and colleagues produced the first study highlighting rapid antidepressant effects of ketamine among patients with major depressive disorder (Berman *et al.* 2000). This report went largely unnoticed until the antidepressant effects of ketamine were replicated a few years later (Zarate *et al.* 2006). Since then, ketamine has received increasing attention in the scientific and medical fields (Souza-Marques *et al.* 2021). Today a PubMed search for ketamine reveals more than 22,000 publications, and a search for ketamine + depression reveals more than 3,700.

From a mechanistic perspective, ketamine has been shown to have a variety of effects on glutamatergic receptors, in particular *N*-methyl-D-aspartate (NMDA) and a-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors, as well as on glutamate release (Aleksandrova *et al.* 2017). These mechanisms of action are among the major reasons why ketamine has received so much attention from the scientific and clinical communities as a potential therapy for AUD. In support of ketamine's utility as a novel treatment for AUD, a study by Dakwar *et al.* (2020) indicated that a single infusion of ketamine significantly reduced the likelihood of heavy drinking, enhanced the likelihood of abstinence, and delayed the time to relapse, particularly when patients also underwent MET. Similarly, a recent study showed that three weekly infusions of ketamine combined with psychological therapy increased the number of days of abstinence from alcohol consumption (although relapse rates were similar between placebo and ketamine groups [Grabski *et al.* 2022]). These studies highlight the potential of ketamine for reducing alcohol drinking and increasing abstinence among people with AUD who receive concomitant personalized behavioral therapy (e.g., MET). Although future studies are indicated to identify optimal ketamine and psychological therapy regimens for AUD, it is plausible that a wide variety of infusion frequencies and dosages adapted to the medical and personal histories of each patient will be necessary to maximize ketamine's therapeutic utility.

Psilocybin

In addition to ketamine, a chemical compound found in mushrooms of the genus *Psilocybe*, psilocybin (which has psychedelic properties), is gaining increasing attention as a potential aid for a variety of psychiatric conditions ranging from depression to AUD and other addictions (Davis *et al.* 2021; Gukasyan *et al.* 2022; Nutt and Carhart-Harris 2021). Fungi like *psilocybin* mushrooms have been on earth for millions of years. One of the most intriguing theories surrounding the origins of psilocybin use postulates that almost 2 million years ago, *Homo erectus* achieved altered states of consciousness from eating mushrooms containing psychedelic compounds (McKenna 1992). Independent of this theory, populations spanning from Siberia to Greece to Central America are known to have used psychedelic mushrooms in rituals to foster unity and emotional and spiritual closeness between community members as well as with higher powers of the universe.

From a mechanistic perspective, two of the primary sites of psilocybin's actions are the serotonin and glutamate systems (Martin-Ruiz *et al.* 2001;

Nichols 2016). The neurobiological effects of psilocybin may in part explain the growing evidence that psilocybin-assisted therapy has important antidepressant and antianxiety effects on individuals with life-threatening cancer, treatment-resistant depression, and/or anxiety. In contrast to ketamine, which has high abuse liability and requires rigorous medical monitoring, psilocybin is relatively easier to manage, monitor, and administer to patients. Thus, psilocybin-assisted therapy has recently been explored as a novel antidepressant treatment (Carhart-Harris *et al.* 2016; Goldberg *et al.* 2020; Griffiths *et al.* 2016; Ross *et al.* 2016). However, clinical trials have emphasized the need for psychological therapy and a controlled setting with health care professionals when using psilocybin as a putative treatment (Davis *et al.* 2021; Gukasyan *et al.* 2022).

With respect to AUD, a 2015 study suggested that psilocybin has therapeutic potential in mitigating alcohol use (Bogenschutz *et al.* 2015). In this pilot study, 10 volunteers with DSM-IV alcohol dependence received orally administered psilocybin in one or two supervised sessions in combination with MET, as well as additional therapy sessions focused on explaining the psilocybin sessions. Although abstinence from alcohol use did not change significantly in the first 4 weeks of observation (before the subjects received psilocybin), abstinence increased significantly following psilocybin administration. Furthermore, the apparent effects of psilocybin on suppressing alcohol use were maintained for up to 36 weeks at follow-up. These observations, albeit preliminary, warrant further study aimed at understanding the potential therapeutic use and risks of psilocybin as an additional therapy to help initiate and maintain alcohol abstinence.

In conclusion, psychedelic compounds like ketamine and psilocybin may offer therapeutic options for patients with a variety of treatment-resistant psychiatric conditions from depression to AUD and other addictions (Nielson *et al.* 2018). Future studies are needed to delineate patient selection criteria and treatment regimens, indications, contraindications, risks, and overall treatment costs for patients with these devastating conditions.

Effects of the Pandemic on Alcohol Use and Treatment for Alcohol Use Disorder

The United States declared the SARS-CoV-2 virus a public health emergency on January 31, 2020. This pandemic changed the relationship many individuals had with alcohol. The protracted stress of the pandemic, and pandemic-related constraints on healthy coping mechanisms such as social gatherings or gym workouts, led many to increase their alcohol use as a coping strategy or as self-medication for pandemic-related increases in depression and anxiety (Capasso *et al.* 2021). Stress is likely to increase alcohol use, whether it derives from social isolation, personal and financial losses, or a large-scale disaster (Grossman *et al.* 2020; Koob *et al.* 2020). Alcohol may provide short-term relief from negative emotional states and thereby reinforce its continued use. However, neuroadaptations occur over time that reduce the relief provided by alcohol and increase the experience of negative affective states when not drinking, thereby creating a heightened vulnerability to further increases in alcohol use (Koob *et al.* 2020). COVID-19-related increases in alcohol consumption that are sustained for more than a year are projected to cause marked increases in liver disease and deaths (Julien *et al.* 2022). Similarly, a Rand Corporation study projected that high levels of stress related to the COVID-19 pandemic, isolation, and unemployment could account for an unprecedented surge in "deaths of despair" caused by alcohol, drugs, and suicide (Petterson *et al.* 2020).

One stark example of the association between the pandemic and alcohol misuse can be found in an analysis of U.S. mortality data from the National Center for Health Statistics. These data showed an average of 8,251 alcohol-related deaths per month in 2020 compared with 6,256 in 2018 and 6,577 in 2019 (White *et al.* 2022). The primary causal factors for 2020 alcohol-related deaths included alcohol-associated liver disease (29.8%), overdose (18.1%), and AUD and withdrawal (15.4%). Whether the increase in pathological alcohol use observed during the pandemic will persist after the pandemic is not yet known. However, studies following people in the 9/11 World Trade Center Health Registry found increased risk of pathological drinking lasting more than a decade after exposure to the 9/11 attacks (Welch *et al.* 2017). These findings suggest that treatment providers may see an unprecedented number of individuals presenting for treatment for AUD and alcohol-related problems.

A unique sequela of the COVID-19 pandemic involved constraints on in-person clinical assessment and treatment to mitigate the spread of COVID-19 infection among patients and practitioners. Interventions to help people cope with an unhealthy relationship with alcohol could not be deferred until the pandemic subsided, in particular given the increased risk of suicide when AUD co-occurs with depression and other serious mental disorders (Chiappini *et al.* 2020). Delivering AUD treatments safely and effectively during the pandemic involved the rapid adoption of telehealth modalities for individuals experiencing ongoing obstacles to in-person treatment, and these strategies have increasingly been incorporated into routine care as pandemic constraints have relaxed.

Telehealth Strategies to Facilitate Pharmacological Treatment of Alcohol Use Disorder

Overview

The use of telehealth strategies to facilitate the identification of and intervention for alcohol misuse was increasing prior to the pandemic and expanded rapidly during the pandemic. Notably, the CDC issued a call in March 2020 for nonemergent medical care to prioritize telehealth consultations. Thus, telehealth modalities proved essential in meeting an increased need for diagnosis and treatment of AUD during the pandemic and is now part of routine postpandemic AUD treatment options. A defining feature of telehealth is that assessments and interventions are conducted remotely. Technologies currently available to facilitate evidence-based treatments of AUD include

telephone and videoconferencing calls, internet-based self-guided programs, smartphone apps, and biosensor monitoring devices (Table 55-3). AA provides a free AA Meeting Guide smartphone app with information on the day, time, and location of in-person and Zoom meetings near the current location of the app user as well as a link to access a selected Zoom meeting. Similarly, the websites of secular mutual support groups (e.g., SMART Recovery, LifeRing Secular Recovery, and Women for Sobriety) currently provide calendars of in-person and virtual Zoom meetings (Bergman *et al.* 2021).

Prior to the pandemic, early studies found support for the efficacy of AUD interventions delivered via teleconferencing as well as a high degree of patient satisfaction with this telehealth modality, especially when transportation and access to treatment are limited (e.g., in rural areas [Campbell *et al.* 2016; Lin *et al.* 2019; Staton-Tindall *et al.* 2014]). Similarly, a pilot study found equivalent efficacy for a self-administered web-based program based on SMART Recovery principles and in-person SMART Recovery participation (Campbell *et al.* 2016). The Hazelden Betty Ford Foundation implemented a pilot virtual intensive outpatient program for 1,446 patients prior to the onset of the pandemic and found treatment outcomes comparable to those of 1,009 outpatients who had received in-person intensive outpatient treatment; results showed increased rates of abstinence, AA attendance, and quality of life (mental and physical) 3 months after discharge (Gliske and Ngo 2020). Of note, patients in the virtual group attended more sessions and had a lower rate of discharge against medical advice than those in the in-person group.

These findings lend support to the acceptability and efficacy of virtual treatment of AUD. In general, fidelity to evidence-based AUD treatments (e.g., MET, CBT, 12-step facilitation therapy, and dialectical behavior therapy) as opposed to general supportive psychotherapy optimizes AUD treatment outcomes, whether treatment is given in person or remotely via telehealth (Kadden *et al.* 1995; Miller and Rollnick 2014; Miller *et al.* 1995; Nowinsky *et al.* 1992). Examples of currently available AUD telehealth tools are provided in the following sections and in Table 55-3.

Websites

The NIAAA Healthcare Professional's Core Resource, launched in Fall 2022, is an online tool that aims to cover the basics of what every healthcare professional needs to know about alcohol (National Institute on Alcohol Abuse and Alcoholism 2022c). It offers free continuing medical education/continuing education credit for 14 educational modules that include a guide to SBIRT, brief interventions, and evidence-based treatments for AUD.

NIAAA has also developed an easy-to-navigate evidence-based online resource for clinicians, patients, and their families called Rethinking Drinking (National Institute on Alcohol Abuse and Alcoholism 2022b). Topics covered include "How much is too much?" and "Thinking about a change?" and are accompanied by probes to help individuals assess their own readiness for change in their alcohol use. The SBIRT model has been adapted for virtual use by clinicians using phone or video conferencing (National Institute on Alcohol Abuse and Alcoholism 2022a). When in an online meeting, the clinician may screen-share modules of the NIAAA Rethinking Drinking website to guide a brief invention using motivational interviewing. Tools for self-monitoring alcohol use are provided on the Rethinking Drinking website, as are strategies for cutting down or quitting. Links are provided to professional associations of AUD treatment specialists, mutual support groups, and the NIAAA Alcohol Treatment Navigator (https://alcoholtreatment.niaaa.nih.gov).

The Treatment Navigator website provides information on AUD and types of evidence-based AUD treatments and on how to find qualified clinicians who provide evidence-based AUD pharmacotherapy and behavioral treatments (National Institute on Alcohol Abuse and Alcoholism 2017). Links are also provided to CBT4CBT (Carroll *et al.* 2008), a proprietary computer-based CBT program to help people stop or reduce alcohol use that can be prescribed by a health care professional in conjunction with pharmacological treatment as part of a comprehensive AUD treatment plan.

The Tempest Online Alcohol Recovery and Support to Quit Drinking program is an 8-week fee-based, feminine-centric approach to recovery that includes elements of evidence-based treatments for AUD (i.e., CBT, dialectical behavior therapy, mindfulness, and peer coaching). A naturalistic outcome study assessed alcohol use and related outcomes among 541 Tempest participants (Moskal *et al.* 2021). Participants were 94.8% female and 94.3% white; 81% had a college degree or higher, and 96.9% had symptoms that met criteria for AUD. Among those participating in 2-month (58.7%), 6-month (47.9%), and 12-month (24.6%) follow-up assessments, a significant reduction from baseline was found in the number of DSM-5 AUD symptoms, alcohol use, and craving, with general improvement in mental and physical health and quality of life. The highly specific demographics of the participants in the Tempest study (i.e., white, educated females) are a reminder that such factors may influence an individual's attitude toward alcohol use and treatment. Cultural competence in understanding the influence of such factors may facilitate building a therapeutic alliance and providing optimal telehealth referrals.

Smartphones

It is estimated that 97% of U.S. adults own a cell phone (Pew Research Center 2021). Text messaging of appointment reminders is widely used in medicine to decrease the frequency of missed appointments. Text messaging can support recovery by transmitting motivational affirmations and relapse prevention support. Smartphones may also be used to set medication reminders, find mutual support meetings, and track alcohol use. Systematic reviews of smartphone apps targeting alcohol use have found few commercially available options that have been scientifically evaluated for efficacy (Colbert *et al.* 2020) or that integrate evidence-based interventions for AUD (Tofighi *et al.* 2019). App features that have face validity include a baseline assessment of alcohol use and subsequent tracking of drinking, geospatial positioning locators of 12-step meetings and AUD treatment programs, and warnings about proximity to locations with increased risk of drinking. Evidence of efficacy was provided for AlcooQuizz, a free-to-download app that provides individuals with a self-assessment of their drinking relative to age-and sex-adjusted norms, current BAC estimate, and drinking limit challenges; data collected may be shared remotely through the app with a treatment provider. A controlled trial involving 977 participants found that those who downloaded the AlcooQuizz app showed a significant reduction in the number of drinks per week at 6-month follow-up relative to a control group not offered any intervention (Bertholet *et al.* 2019).

Apps for self-monitoring alcohol use can help keep people engaged and mindful of alcohol use goals, in particular those with less severe alcohol problems. However, there is little evidence of efficacy for AUD of greater severity when such apps are used without the supervision and personalized care of treatment professionals (Kaner *et al.* 2017). Clinicians who become familiar with the apps their patients are using will be better able to use app data to discuss patients' progress and relapse risk. Standards for medical devices and cybersecurity also apply to app data shared with clinicians to ensure data security and patient privacy.

Biosensor Devices

Biosensor devices can be used to monitor physiological parameters such as heart rate and to measure chemical levels in the body, such as BAC. BACtrack (KHN Solutions, Inc.; San Francisco, California) is an app that pairs with an OTC Bluetooth-enabled smartphone keychain breathalyzer that can generate detailed drinking data and BAC readings. It can be used by individuals to estimate their BAC, what it means for their level of intoxication and motor skills, and how long it will take to achieve a zero BAC. Data from random or scheduled BAC determinations (e.g., daily at

8:00 p.m.) can be shared remotely via the BACtrack smartphone app with treatment providers to monitor recovery and optimize treatment response (e.g., by identifying risky times for drinking and implementing proactive coping strategies).

The Secure Continuous Remote Alcohol Monitor (SCRAM) is an ankle bracelet that can be worn continuously to monitor transdermal alcohol content every half hour and more frequently when a heavy drinking episode or tampering with the device is detected. Alcohol-related data are uploaded to a secure web-based server. The SCRAM is the only device to measure transdermal alcohol content that is currently commercially available, although flexible wristwatch-like models (e.g., the BACtrack Skyn) are in various stages of development.

Smartphones may be paired with a smartwatch to electronically monitor pulse rate data and share them with a treatment provider (e.g., by using the sharing function on the Apple Health app). These heart rate data can be valuable in remotely assessing risk of clinically significant alcohol withdrawal. Such devices can also collect sleep and activity data that may be electronically shared with a treatment provider to assess behavioral changes that may signal an increased risk of drinking relapse. As an alternative, patients can obtain an OTC digital pulse and blood pressure monitor at a pharmacy or online and show the current reading to their clinician during video appointments.

Bluetooth-enabled medication management systems and apps (e.g., the LiveFine Smart WiFi Automatic Pill Dispenser) can alert patients and/or clinicians to missed doses of AUD medications and deliver systematic reminders to ensure adherence to pharmacological treatment.

Telehealth as a Mainstream Treatment Modality for Alcohol Use Disorder

Surveys of more than 6 million employee health plan beneficiaries conducted in 2019 and 2020 found a 20-fold increase in the utilization of telemedicine after the onset of the pandemic (Cantor *et al.* 2021). Telehealth now offers critical access to AUD screening and intervention for groups that have seen pandemic-related increases in AUD, such as women caring for young children in the home for whom in-person treatment is prohibitive because of child care and transportation constraints (Busch *et al.* 2021).

Telehealth applications for treating AUD are evolving rapidly. Many providers were not prepared to quickly launch a telehealth practice and had to learn--and teach their patients--how to establish a quiet, well-lit, private space and ensure adequate bandwidth and transmission speed for Zoom calls. A backup plan in case of technology failure had to be established, as did strategies to address privacy issues. APA and the American Telemedicine Association provided general guidelines in "Best Practices in Videoconferencing-Based Telemental Health April 2018" (Shore *et al.* 2018). Telehealth for AUD also raised concerns among practitioners about liability, reimbursement, and regulatory issues at the state and federal levels. SAMHSA provided information to address these issues in its evidence-based resource guide *Telehealth for the Treatment of Serious Mental Illness and Substance Use Disorder* (Substance Abuse and Mental Health Services Administration 2021b). This guide also reviews the extant literature and research findings related to telehealth treatment of AUD and related disorders and concludes that telehealth is effective across the continuum of care for AUD, including screening, pharmacotherapy, behavioral treatments, recovery support, and crisis management. No differences in treatment efficacy, retention, or attendance rates, or in patients' level of satisfaction, were found between in-person and telehealth treatments.

Some patients with AUD may prefer to have face-to-face meetings with counselors and mutual support groups and to receive their medication, give urine and breath samples, and get feedback and encouragement in person. But many patients prefer the convenience, reduced stigma, and expanded access to care that telehealth provides while reducing the burden of travel and associated time off from work and need for child care. Telehealth reduces geographic barriers to care as well as barriers imposed by psychological and physical disabilities.

Combining pharmacological treatment of AUD with evidence-based telehealth interventions (see Table 55-3) may optimize AUD treatment outcomes by allowing clinicians to work smarter with continuously updated information from biosensor devices, smartphone apps, and online medication monitoring systems. Incorporating technology into an AUD treatment plan could expand practitioners' caseload capacity by decreasing their travel time to treatment settings, increasing their flexibility in scheduling, and expanding AUD specialty services to general practice settings. Telehealth AUD treatment teams could facilitate more strategic utilization of AUD specialty care services in a hub-and-spoke model that coordinates services and provides for continuity of care.

Research is needed to determine the adequate duration of telehealth treatments, any optimal degree of integration with traditional in-person treatments, and the sustainability of effects. Of note, an analysis of smartphone app data from a cohort of 152 patients who completed AUD residential treatment generated a model with good predictability of relapse risk within the coming week (Chih *et al.* 2014). Future analyses of large app data sets may further identify factors signaling increased risk of drinking relapse and patients who may benefit from immediate personalized support to mitigate their risk. Now that safe and effective telehealth modalities have been widely implemented for the treatment of AUD during the pandemic, consensus best practice recommendations should be developed and systematically implemented in training programs to ensure AUD telehealth continues to be available and is delivered in a safe and effective manner. Future work is

needed to understand the extent to which COVID-19-related changes in telehealth utilization may permanently impact AUD treatment, including identifying barriers and facilitators at the patient, provider, health care system, insurer, and legislative levels (Cantor *et al.* 2021). Pharmacological and behavioral telehealth interventions could potentially reach millions with AUD who currently go untreated as well as offer monitoring and support for those in recovery (e.g., with just-in-time interventions).

CHAPTER 56

Treatment of Personality Disorders

Eric Hollander, M.D.
Tarini Vats, M.D.
Nilifa Desilva, M.P.H.

Personality disorders are among the most challenging conditions faced by clinicians. The two main approaches to treating personality disorders are psychosocial treatment and medication. Psychotherapy continues to be the treatment foundation for all personality disorders, and psychotherapy studies on the whole have shown improvement with treatment two to four times greater than the improvement seen in control conditions (Perry and Bond 2000). The main indications for using medications in treating personality disorders are periods of decompensation, crises, and hospitalizations; the need for longer-term management of symptom clusters that are maladaptive and may be responsive to medication; and the reappearance or worsening of comorbid conditions. The underlying rationale for medication use in personality disorders is that associated behavioral traits might have neurobiological and psychological correlates (Oquendo *et al.* 2005; Simeon *et al.* 1992).

In this chapter we summarize the literature to date on the pharmacological treatment of personality disorders. We begin with a brief overview of current conceptualizations of personality and what constitutes a personality disorder, followed by a discussion of the treatment of Cluster B disorders (which have the largest evidence base), Cluster A disorders, and Cluster C disorders. Findings from neuroimaging, neuroendocrine, and cognitive-behavioral studies pertinent to the understanding of personality disorders are summarized. The chapter concludes with a brief overview of emerging areas of research and their implications for our understanding of the pathophysiology and treatment of personality disorders.

Models of Personality

Although nobody doubts the existence of personality, what constitutes its disordered form has been controversial. There is little disagreement on the limitations of the current categorical classification of personality disorders, but consensus on a unified model has been lacking. Much of the debate has centered on dimensional versus categorical models of personality disorders. The alternative dimensional model for personality disorders in Section III of DSM-5 (American Psychiatric Association 2013) has two main criteria: impairment in personality functioning and one or more pathological personality traits.

The founder of personality psychology, Gordon Allport (1937), in one of the earliest conceptualizations of personality disorders, theorized that "personality 'is' something and personality 'does' something" (p. 48). In the more than 80 years since then, research into what personality "is" (i.e., trait structural models) has dominated the field (Ro *et al.* 2013). Recently there has been increased attention to what personality "does"--that is, the functional aspects of personality and how it serves to adapt individuals' behaviors to their situations (Ro and Clark 2009). Distinguishing personality functioning from traits is important conceptually, because simply having extreme traits is not necessarily pathological. From an evolutionary perspective, Livesley and Jang (2000) theorized that severe personality pathology reflects a failure of three adaptive systems: a self-system (i.e., the development of a stable concept of self and, correspondingly, of others) and two other-systems (i.e., the capacity for close personal relations and intimacy, and the ability to function effectively at a societal level). The consequence of this system failure is an inability to handle major life tasks, in effect Sigmund Freud's *lieben und arbeiten* (to love and to work).

The heterogeneity and absence of evidence to support treatment of individual personality disorders led researchers to largely ignore specific DSM Axis II personality disorder categories and adopt a more parsimonious approach to treatment, focusing instead on dimensions of psychopathology that cut across various personality disorders. The limitations of categorical models led to the development of a trait-based algorithm initially proposed by Siever and Davis (1991) and further developed by Soloff (1998). This new algorithm posited that four dimensions cutting across all personality disorder categories--affective instability, anxiety-inhibition, cognitive-perceptual disturbances, and impulsivity-aggression--should be studied rather than individual symptom clusters or diagnoses. This model has served as a dominant framework for understanding the evidence regarding the effects of medication on personality disorders (Bateman *et al.* 2015).

The diagnosis and classification of personality disorders are shifting toward a more dimensional model of classification (Widiger and Simonsen 2005). Although several models were proposed in DSM-IV-TR (American Psychiatric Association 2000), the model included in Section III of DSM-5 as an alternative to current categorical classifications is based on the empirically supported Five Factor Model, which includes the following broad domains: negative affectivity (vs. emotional stability), detachment (vs. extraversion), antagonism (vs. agreeableness), disinhibition (vs. conscientiousness), and psychoticism (vs. lucidity) (Widiger and Costa 1994). This model, in contrast to other models, was felt to adequately cover the full range of personality disorder symptomatology and has amassed the most empirical support (Widiger and Costa 1994). Compared with other models, it was felt to more accurately reflect normal as well as abnormal personality functioning and to better account for the symptoms and traits of DSM-IV-TR personality disorders (Clark 2007). The aspects of personality functioning considered to be most important to people across all cultures and languages when they describe themselves and others pertain to interpersonal relatedness, a domain thought to form the core of personality disorders (Pincus 2005) and captured by the two factors of extraversion and agreeableness.

Despite the formidable challenges in understanding what constitutes disordered personality features and their optimal treatment approach, reasons for optimism exist. The traditional view that personality disorders are necessarily chronic, stable over time, and marked by poor outcomes has been challenged in recent years in light of the fact that the more serious epiphenomena of disorders such as borderline personality disorder (BPD), including serious suicide attempts, impulsive behaviors, misuse of services, and aggressive outbursts, all show improvement with treatment. Findings from longitudinal studies of personality disorders such as the Collaborative Longitudinal Personality

Disorders Study and the McLean Study of Adult Development have challenged the traditional entrenched pessimism about the poor prognoses of personality disorders such as BPD (Gunderson *et al.* 2011; Zanarini *et al.* 2010). Such findings have driven the removal from DSM-5 of the separate Axis II category altogether as well as the introduction of terms such as *remission* and *relapse* to the conceptualization of personality disorders.

Pharmacotherapy for Cluster B Personality Disorders

Almost all of the clinical research trials examining medication treatments for personality disorders have studied BPD. The symptom clusters typically targeted in this condition, although varying from trial to trial in how they are defined and assessed, are dysregulated impulsivity and aggression, affective lability and hyperreactivity, cognitive-perceptual disorganization, anxiety, and dissociation. Dysregulation of impulses and affective instability are widely viewed as the hallmark symptoms of BPD. A retrospective chart review of 87 inpatients diagnosed with BPD between 2008 and 2012 found that 94% of all BPD inpatients received at least one psychotropic drug at the time of discharge. Overall prescription of psychotropic drugs was greater in this cohort compared with a 1996-2004 cohort (Timaus *et al.* 2019). Studies suggest that despite the limitations in our knowledge of treatments for BPD, drugs are very frequently prescribed, and polypharmacy is common, with antipsychotics, antidepressants, and mood stabilizers being the most commonly prescribed medication groups (Bridler *et al.* 2015; Knappich *et al.* 2014; Riffer *et al.* 2019; Zanarini *et al.* 2004b). One recent, rather selective review of randomized controlled trials testing drug treatments for BPD found a lack of sufficient evidence to support the use of pharmacological treatments for BPD (Stoffers-Winterling *et al.* 2020), although data from our review presented here suggest a more nuanced role for medications. Findings from this review did not support fluoxetine as a beneficial treatment option for the prevention of suicidal behavior in people with BPD. A real-world effectiveness study suggested that lamotrigine likewise is not a clinically effective treatment for BPD (Crawford *et al.* 2018). The review by Stoffers-Winterling *et al.* (2020) clearly indicated a need for more randomized controlled trials to evaluate the drugs, including atypical antipsychotics, that are most commonly used by people with BPD but also by people presenting with distinct comorbid conditions.

Conventional Antipsychotics

Abnormalities in dopamine signaling are thought to underlie the cognitive-perceptual symptoms of BPD, which include paranoia, perceptual aberrations, and subtle thought disorder, and this understanding forms the rationale for the use of antipsychotics to treat the disorder. BPD patients have been found to have higher plasma and cerebrospinal fluid levels of the dopamine metabolite homovanillic acid, and dopamine receptor genetic polymorphisms have been found to interact with traumatic attachment stressors to produce the attachment insecurity and disorganization thought to be integral to BPD (Steele and Siever 2010). On the whole, studies of conventional antipsychotics suggest significant improvements in anger with haloperidol and in suicidality with flupentixol decanoate, whereas effects on psychosis, irritability, and affective symptoms have been variable (Table 56-1). Any benefits of older antipsychotic agents must be weighed against these agents' well-established propensity to cause extrapyramidal symptoms and tardive dyskinesia.

TABLE 56-1. Summary of medication treatment trials with antipsychotics in borderline personality disorder (BPD)

Study	Subjects	Antipsychotic(s)	Other agent(s)	Duration	Outcome
Typical antipsychotics					
Leone 1982	80 BPD	Loxapine	Chlorpromazine	6 weeks	Improvement with both agents; greater improvement in depression and anger-hostility with loxapine
Montgomery and Montgomery 1982	30 BPD	Depot flupentixol	Placebo	4-6 months	Decrease in suicide attempts
Serban and Siegel 1984	16 BPD, 14 SztPD, 16 both	Thiothixene, haloperidol	--	12 weeks	Improvement in cognition, paranoia, anxiety, depression, social function with both agents (thiothixene > haloperidol)
Goldberg *et al.* 1986	17 BPD, 13 SztPD, 20 both	Thiothixene	Placebo	12 weeks	Decreased psychosis, anxiety
Soloff *et al.* 1986, 1989	35 BPD, 4 SztPD, 51 both	Haloperidol	Amitriptyline, placebo	5 weeks	Improvement in hostile depression, impulsivity, global functioning with haloperidol; improvement in depression but worsening on other measures with amitriptyline
Cowdry and Gardner 1988	16 BPD	Trifluoperazine	Alprazolam, carbamazepine, tranylcypromine, placebo	6-week crossover	Improvement but tolerability issues with trifluoperazine; greatest improvement on mood, anxiety, impulsivity with tranylcypromine; decreased severity of behavioral dyscontrol with carbamazepine; increased behavioral dyscontrol and suicidality with alprazolam
Soloff *et al.* 1993	42 BPD, 66 BPD and SztPD	Haloperidol	Phenelzine, placebo	5 weeks	Minimal improvement with haloperidol; improvement in depression, anxiety,

Note. SztPD = schizotypal personality disorder.

Study	Subjects	Antipsychotic(s)	Other agent(s)	Duration	Outcome
					anger, hostility with phenelzine
Cornelius *et al.* 1993	Continuation of Soloff *et al.* 1993 study			16-week extension	Reduced irritability but worsening of depression, leaden paralysis with haloperidol; modest improvement in depression and irritability with phenelzine
Atypical antipsychotics					
Frankenburg and Zanarini 1993	15 refractory BPD	Clozapine	--	2-9 months	33% overall improvement
Schulz *et al.* 1998	BPD	Risperidone	Placebo	8 weeks	Modest improvement, no better than placebo
Schulz *et al.* 1999	11 BPD (7 also SztPD)	Olanzapine	--	8 weeks	Generally modest to moderate improvement
Zanarini and Frankenburg 2001	28 BPD	Olanzapine	Placebo	6 months	Decreased anger, paranoia, anxiety, interpersonal sensitivity
Rocca *et al.* 2002	15 BPD with marked aggression	Risperidone	--	8 weeks	Decreased aggression, improved global functioning
Bogenschutz and Nurnberg 2004	40 BPD	Olanzapine	Placebo	12 weeks	Greater overall improvement in BPD severity
Villeneuve and Lemelin 2005	23 BPD	Quetiapine	--	12 weeks	Improved impulsivity, other measures, global function
Nickel *et al.* 2006	52 BPD	Aripiprazole	Placebo	12 weeks	Improvement on all outcome measures, including depression, anger, anxiety
Bellino *et al.* 2006	14 BPD	Quetiapine	--	12 weeks	Improvement especially in impulsiveness/aggressiven

Note. SztPD = schizotypal personality disorder.

Study	Subjects	Antipsychotic(s)	Other agent(s)	Duration	Outcome
					ess
Perrella *et al.* 2007	29 BPD	Quetiapine	--	12 weeks	Improvement especially in aggression and low mood
Schulz *et al.* 2007	314 BPD	Olanzapine	Placebo	12 weeks	No difference in overall symptom improvement between olanzapine and placebo groups
Zanarini *et al.* 2007	451 BPD	Low-dosage olanzapine (2.5 mg/day), moderate-dosage olanzapine (5-10 mg/day)	Placebo	12 weeks	Greater overall improvement for moderate-dosage olanzapine compared with low-dosage olanzapine and placebo
Linehan *et al.* 2008	24 BPD	Olanzapine	Placebo	6 months	Greater reductions in irritability and aggression with olanzapine
Pascual *et al.* 2008	60 BPD	Ziprasidone	Placebo	12 weeks	No difference in overall symptom improvement between groups
Zanarini *et al.* 2011	451 BPD	Olanzapine	Placebo	12 weeks	Significant reduction in overall BPD severity
Bellino *et al.* 2011	18 BPD	Paliperidone extended release	--	12 weeks	Significant reduction in overall BPD severity
Black *et al.* 2014	95 BPD	Quetiapine	Placebo	8 weeks	Significant reduction in overall BPD severity
Lee *et al.* 2016	95 BPD	Quetiapine	Placebo	8 weeks	Reduction in levels of overall psychological distress, interpersonal sensitivity, depression, hostility compared with placebo

Note. SztPD = schizotypal personality disorder.

Study	**Subjects**	**Antipsychotic(s)**	**Other agent(s)**	**Duration**	**Outcome**
Bozzatello *et al.* 2017	51 BPD	Asenapine	Olanzapine	12 weeks	Asenapine was found to be more effective than olanzapine at treating affective instability; olanzapine demonstrated better efficacy for treating paranoid ideation and dissociation
Rohde *et al.* 2018	25,916 BPD	Clozapine	--	2 years	Significant reduction in psychiatric admissions, psychiatric bed-days, number of patients with intentional self-harm or overdose

Note. SztPD = schizotypal personality disorder.

Atypical Antipsychotics

Atypical antipsychotics have received increased attention in recent years (see Table 56-1). On the whole, BPD treatment studies using atypical antipsychotics have shown improvements in affective instability, impulsivity, psychosis, and interpersonal dysfunction. In clinical practice, it appears that atypical antipsychotics are prescribed more frequently than conventional agents because of their greater tolerability and lower risks of extrapyramidal symptoms and tardive dyskinesia. A number of studies have examined olanzapine in the treatment of BPD (see Table 56-1). The largest study to date was conducted by Zanarini *et al.* (2011). In this 12-week randomized, double-blind, placebo-controlled trial, 451 outpatients with DSM-IV (American Psychiatric Association 1994) BPD received olanzapine 2.5 mg/day (*n* = 150), olanzapine 5-10 mg/day (*n* = 148), or placebo (*n* = 153). Olanzapine 5-10 mg/day showed a clinically modest advantage over placebo in the treatment of overall borderline psychopathology. Treatment-emergent adverse events included somnolence, fatigue, increased appetite, and weight gain (Zanarini *et al.* 2011). A 12-week open-label extension of the study found sustained improvements over longer durations (Zanarini *et al.* 2012).

Another large-scale placebo-controlled study comparing the efficacy and tolerability of low and moderate dosages of extended-release quetiapine in 95 adults with BPD found that participants in the low-dosage quetiapine (150 mg/day) group had significant improvement on measures of overall BPD severity compared with those in the placebo group (Black *et al.* 2014). Moreover, 82% in the low-dosage quetiapine group were rated as responders compared with 74% in the moderate-dosage (300 mg/day) group and 48% in the placebo group. Treatment-emergent adverse events included sedation, changes in appetite, and dry mouth. The overall completion rate for the 8-week double-blind treatment phase was 67% (67% for the low-dosage quetiapine group, 58% for the moderate-dosage quetiapine group, and 79% for the placebo group) (Black *et al.* 2014). Furthermore, an analysis of this study found that both low and moderate dosages of quetiapine were effective at reducing levels of overall psychological distress, interpersonal sensitivity, depression, and hostility compared with placebo (Lee *et al.* 2016).

A 2-year mirror-image study among 25,916 patients with BPD investigating the effects of clozapine showed that clozapine was associated with a significant reduction in psychiatric admissions per patient, from 2.52 to 2.00, and a significant reduction in psychiatric bed-days, from 190.08 to 65.95. The study also found that the number of patients with intentional self-harm or overdose decreased significantly, from 189 to 114, after clozapine initiation (Rohde *et al.* 2018). An open-label pilot study of asenapine versus olanzapine for the treatment of BPD found asenapine to be more effective than olanzapine in treating affective instability. Although olanzapine demonstrated better efficacy in treating paranoid ideation and dissociation, the study was underpowered to detect a difference between the two groups on the dissociation and paranoid ideation domain (Bozzatello *et al.* 2017).

Antidepressants

Although older antidepressant medications, including tricyclic antidepressants (TCAs) and monoamine oxidase inhibitors (MAOIs), have shown modest efficacy in improving affective symptoms of BPD (Cornelius *et al.* 1993; Cowdry and Gardner 1988; Soloff *et al.* 1993), both TCAs and MAOIs pose serious risks of overdose and have the potential for adverse events that are of particular concern in this unstable, impulsive population.

BPD studies with selective serotonin reuptake inhibitors (SSRIs) have yielded mixed findings. Whereas some older studies suggested statistically significant superiority of SSRIs over placebo in BPD (Coccaro and Kavoussi 1997; Markovitz 1995; Salzman *et al.* 1995), more recent controlled studies with SSRIs have shown either no difference from placebo or an additional benefit over placebo only when SSRIs are used to augment standard treatments such as dialectical behavior therapy (Simpson *et al.* 2004). SSRI monotherapy also demonstrated no statistical benefit over atypical antipsychotic monotherapy for depression and impulsive aggression (Zanarini *et al.* 2004a). Results from a Delphi study conducted by 18 international experts suggested a valuable role for SSRIs in the treatment of affective instability among older adults with BPD, with the first-choice SSRI being either sertraline or citalopram. The experts also agreed that SSRIs can be used as a second choice for treating impulsive behavior in this patient group (Schulkens *et al.* 2021). BPD studies with serotonin-norepinephrine reuptake inhibitors such as venlafaxine (Markovitz and Wagner 1995) and the newer agent duloxetine (Bellino *et al.* 2010) have also shown modest efficacy in treating affective symptoms (irritability, anger) and impulsive behaviors (self-injury), but these trials were limited by their open-label design and small sample sizes. Ketamine has recently received attention in the treatment of BPD because of its demonstrated efficacy in decreasing depression and suicidality in individuals with depression. Preliminary results from an ongoing trial of intravenous ketamine in BPD found that depression and suicidality decreased significantly in responders compared with nonresponders following treatment, although comparison of responders and nonresponders is not an optimal study design. Overall, the early results suggest that people with BPD may potentially respond to ketamine and that ketamine appears to be well

tolerated among this group (Null *et al.* 2019). Studies of antidepressant treatment of BPD are summarized in Table 56-2.

TABLE 56-2. Summary of medication treatment trials with antidepressants in borderline personality disorder (BPD)

Study	**Subjects**	**Antidepressant(s)**	**Other agent(s)**	**Duration**	**Outcome**
Soloff *et al.* 1986, 1989	35 BPD, 4 SztPD, 51 both	Amitriptyline	Haloperidol, placebo	5 weeks	Improvement in depression but worsening on other measures with amitriptyline; improvement in hostile depression, impulsivity, global functioning with haloperidol
Soloff *et al.* 1993	42 BPD, 66 BPD and SztPD	Phenelzine	Haloperidol, placebo	5 weeks	Improvement in depression, anxiety, anger, hostility with phenelzine; minimal improvements with haloperidol
Cornelius *et al.* 1993	Continuation of Soloff *et al.* 1993 study			16-week extension	Modest improvement in depression and irritability with phenelzine; reduced irritability but worsening of depression, leaden paralysis with haloperidol
Cowdry and Gardner 1988	16 BPD	Tranylcypromine	Alprazolam, carbamazepine, trifluoperazine, placebo	6-week crossover	Greatest improvement in mood, anxiety, impulsivity with tranylcypromine; decreased severity of behavioral dyscontrol with carbamazepine; increased behavioral dyscontrol and suicidality with alprazolam; improvement but tolerability issues with trifluoperazine
Markovitz *et al.* 1991	22 BPD or SztPD	Fluoxetine	--	12 weeks	Marked decline in self-mutilation, depression,

Note. SztPD = schizotypal personality disorder.

Study	Subjects	Antidepressant(s)	Other agent(s)	Duration	Outcome
					anxiety, interpersonal sensitivity, paranoia
Markovitz 1995	23 BPD	Sertraline	--	12 weeks	Half of subjects showed improvement in self-injury, anxiety, depression, suicidality
	Continuation of study			1 year	Decline in depression (56% of subjects) and self-injury (93%)
Kavoussi *et al.* 1994	9 personality disorder with impulsive aggression	Sertraline	--	8 weeks	Decreases in impulsive aggression
Markovitz 1995	17 BPD	Fluoxetine	Placebo	14 weeks	Global improvement on all measures
Salzman *et al.* 1995	27 BPD or BPD traits	Fluoxetine	Placebo	12 weeks	Decreases in anger, depression
Markovitz and Wagner 1995	45 BPD	Venlafaxine	--	12 weeks	40% global improvement, less self-injury
Coccaro and Kavoussi 1997	40 impulsive-aggressive personality disorder (one-third BPD), no major depressive disorder	Fluoxetine	Placebo	12 weeks	Marked decrease in aggression and irritability irrespective of changes in anxiety/depression
Rinne *et al.* 2002	38 BPD	Fluvoxamine	Placebo	6 weeks	Improvement in rapid mood shifts but not impulsivity or aggression
Simpson *et al.* 2004	20 BPD	Fluoxetine	Placebo	12 weeks	No significant additional benefit of adding fluoxetine to dialectical behavior therapy

Note. SztPD = schizotypal personality disorder.

Study	Subjects	Antidepressant(s)	Other agent(s)	Duration	Outcome
Zanarini *et al.* 2004a	45 BPD	Fluoxetine	Olanzapine, fluoxetine + olanzapine	8 weeks	Olanzapine and fluoxetine + olanzapine superior to fluoxetine monotherapy in reducing depression and impulsive aggression, but effect not statistically significant
Bellino *et al.* 2010	18 BPD	Duloxetine	--	12 weeks	Significant effects on impulsivity, anger, affective dysregulation

Note. SztPD = schizotypal personality disorder.

Mood Stabilizers

Mood stabilizers are known to calm excitatory neurotransmission, but the various agents differ in terms of their mechanism of action and effects on GABAergic and glutamatergic signaling mechanisms. As a class, mood stabilizers have gained increasing attention as a medication for the treatment of BPD symptoms, demonstrating moderate effect sizes on impulsive aggression, affective instability, self-injurious behaviors, and overall functioning.

Early studies supported a role for lithium in BPD (Rifkin *et al.* 1972). In a single small controlled study (Links *et al.* 1990), 17 subjects with BPD received 6 weeks each of lithium, the TCA desipramine, and placebo in a randomized crossover design, and 10 subjects completed at least two medication trials. Neither medication was better than placebo for depressive symptoms, although lithium led to a significant decrease in anger and suicidality according to clinician but not patient perception.

Anticonvulsants are used more widely than lithium in the treatment of BPD symptoms. Early studies with carbamazepine reported mixed findings, with some showing improvement in behavioral dyscontrol (Cowdry and Gardner 1988) and others showing no significant improvement with carbamazepine treatment (de la Fuente and Lotstra 1994) compared with placebo.

More recently, anticonvulsant studies have focused on valproate and newer anticonvulsants. In one placebo-controlled trial, 16 outpatients with BPD were treated for 10 weeks with valproate or placebo (Hollander *et al.* 2001). Global improvement was significant by two measures in patients treated with valproate, but the small sample size and high dropout rate precluded statistically significant findings. In another controlled study, valproate's efficacy was examined in 30 women with comorbid BPD and bipolar II disorder over 6 months of treatment (Frankenburg and Zanarini 2002). Valproate at an average dosage of 850 mg/day was well tolerated and resulted in significantly greater improvement in interpersonal sensitivity, hostility/anger, and aggression compared with placebo.

A larger placebo-controlled multicenter trial of valproate showed some efficacy for impulsive aggression in Cluster B personality disorders (Hollander *et al.* 2003). In this study, 91 outpatients selected for the presence of prominent impulsive aggression and the absence of bipolar I disorder or current major depressive disorder were randomly assigned to 12 weeks of treatment with placebo or valproate (mean dosage of 1,400 mg/day). Valproate was well tolerated overall, with only 17% of participants discontinuing because of valproate-related adverse events. The main finding of the study was a significant decrease in impulsive aggression in the last month of treatment, with valproate treatment reducing irritability, impulsive behaviors, and overall aggression, including verbal assault, assault against objects, and assault against others (Hollander *et al.* 2003).

Controlled studies have focused on lamotrigine (200 mg/day) and topiramate (200-250 mg/day) and suggest that both agents may offer therapeutic benefits in terms of treating affective instability and impulsivity in BPD. Lamotrigine (at a target dosage of 200 mg/day) demonstrated efficacy in treating impulsivity, affective symptoms, and aggression in BPD (Tritt *et al.* 2005). Long-term follow-up studies suggested that the benefits of lamotrigine are sustained and that it is an effective and relatively safe agent for longer-term treatment of aggression in women with BPD (Leiberich *et al.* 2008). However, results from a placebo-controlled randomized trial of lamotrigine in adults with BPD found no evidence to support the use of lamotrigine for treating the core symptoms of BPD (Crawford *et al.* 2018). Topiramate is another agent that has demonstrated efficacy for certain dimensions of BPD, such as anger (Loew *et al.* 2006; Nickel *et al.* 2004, 2005). Follow-up studies of topiramate support its efficacy long-term (Loew and Nickel 2008; Nickel *et al.* 2006). BPD treatment trials with mood stabilizers are summarized in Table 56-3.

TABLE 56-3. Summary of medication treatment trials with mood stabilizers in borderline personality disorder (BPD)

Study	Subjects	Mood stabilizer(s)	Other agent(s)	Duration	Outcome
Rifkin *et al.* 1972	21 emotionally unstable character disorder	Lithium	Placebo	6 weeks	Decreased mood lability
Cowdry and Gardner 1988	16 BPD	Carbamazepine	Trifluoperazine, tranylcypromine, alprazolam, placebo	6-week crossover	Decreased severity of behavioral dyscontrol with carbamazepine; greatest improvement in mood, anxiety, impulsivity with tranylcypromine; increased behavioral dyscontrol and suicidality with alprazolam; improvement but tolerability issues with trifluoperazine

Study	**Subjects**	**Mood stabilizer(s)**	**Other agent(s)**	**Duration**	**Outcome**
Links *et al.* 1990	17 BPD	Lithium	Desipramine, placebo	6-week crossover	No significant improvement in depression with lithium or desipramine; trend toward improvement in anger and suicidality (lithium > desipramine); clinician-rated overall improvement (lithium > desipramine)
de la Fuente and Lotstra 1994	20 BPD without depression	Carbamazepine	Placebo	4 weeks	No effect for depression, behavioral dyscontrol, global symptoms
Stein *et al.* 1995	11 BPD	Valproate	--	8 weeks	Modest benefit; half responders; less depression, anxiety, anger, impulsivity, rejection sensitivity
Pinto and Akiskal 1998	8 BPD without depression	Lamotrigine	--	1 year	Two discontinued; three robust global responders with decreased impulsivity and suicidality
Frankenburg and Zanarini 2002	30 BPD	Valproate	Placebo	6 months	Significant improvement in hostility, anger, aggression, interpersonal sensitivity
Hollander *et al.* 2001	16 BPD	Valproate	Placebo	12 weeks	Reduction in interpersonal problems, depression; some improvement in anger (not statistically significant)
Hollander *et al.* 2003	91 impulsive-aggressive Cluster B	Valproate	Placebo	12 weeks	Significant decrease in impulsive aggression

Study	Subjects	Mood stabilizer(s)	Other agent(s)	Duration	Outcome
Nickel *et al.* 2004	29 male BPD	Topiramate	Placebo	8 weeks	Decreased anger, significant weight loss
Nickel *et al.* 2005	42 male BPD	Topiramate	Placebo	8 weeks	Decreased anger, weight loss
Tritt *et al.* 2005	24 female BPD	Lamotrigine	Placebo	8 weeks	Decreased anger, no weight changes
Loew *et al.* 2006	56 female BPD	Topiramate	Placebo	10 weeks	Improvements in interpersonal sensitivity, anxiety, quality of life, weight loss
Crawford *et al.* 2018	20 BPD	Valproate extended release	--	12 weeks	Overall improvement, decreased irritability and aggression
Simeon *et al.* 2007	276 BPD	Lamotrigine	Placebo	52 weeks	Results suggest that treatment with lamotrigine is neither cost-effective nor clinically effective

Other Medications and Agents

Despite their widespread use, benzodiazepines on the whole are not recommended for use in the treatment of BPD because of their risk of worsening impulsivity and suicidality (Cowdry and Gardner 1988). Studies using the a_2-adrenergic agonist clonidine showed its efficacy in the treatment of comorbid PTSD and BPD (Ziegenhorn *et al.* 2009) and suggested a role for clonidine in the treatment of hyperarousal and sleep disturbances associated with BPD. Finally, several randomized controlled trials support the use of omega-3 fatty acids in reducing aggression and affective symptoms in patients with moderate to severe BPD (Zanarini and Frankenburg 2003).

Future Directions for Research, Including Neuropeptides and Other Agents

Drugs are routinely prescribed in clinical practice for the treatment of BPD, although no psychotropic medication has been FDA approved for this disorder. Although more controlled studies on these medications in BPD have become available in recent years, there is general agreement among the reviews in this field that the evidence is weak because of the severe methodological limitations of most studies. Small sample sizes, different gender proportions, heterogeneous selection criteria and assessment instruments, and high rates of dropout are the most relevant limitations. In addition, the mean duration of the trials is too short (32 days to 24 weeks) and insufficient to draw conclusions about the long-term efficacy and tolerability of medications in a long-lasting disorder such as BPD. For many drugs, most studies are open-label trials, which have limited clinical meaning because there is significant evidence of spontaneous changes in BPD symptoms over time. Current treatment guidelines diverge on the role of medications in BPD, which produces uncertainty among clinicians (Bozzatello *et al.* 2020).

Psychopharmacological research in patients with BPD has centered on neuropeptides, including opioids, oxytocin, vasopressin, and neuropeptide Y, all of which modulate complex networks of neurotransmitter systems and facilitate the coordination of affective signaling and behaviors. BPD has been conceptualized as being related to disturbed attachment, and thus oxytocin, vasopressin, and opioids may be of particular relevance for treating BPD, given the developmental role of these neuropeptides in attachment and the relationship between attachment security and stable social cognitive representations of self and other (Fonagy and Luyten 2009; Stanley and Siever 2010).

297

298

299

In the past decade, a shift from a high predominance of prescribing antidepressants to the present-day preference for mood stabilizers and second-generation antipsychotics has been observed. Since 2010, no trials have been conducted in patients with BPD to assess the efficacy and tolerability of antidepressants. Recent systematic reviews have found insufficient evidence to support the prescribing of these drugs to BPD patients, except in the case of comorbidity with depression or anxiety disorders. In contrast, more recent controlled trials have indicated that mood stabilizers (valproate, topiramate, and lamotrigine) and second-and third-generation antipsychotics (olanzapine, quetiapine, and aripiprazole) can significantly affect core symptoms of BPD, such as impulsive-behavioral dyscontrol, affective instability, and cognitive-perceptual symptoms. First-generation antipsychotics have failed to demonstrate effects on BPD symptoms, except for reducing impulsive-aggressive behaviors during acute states, and adverse effects greatly limit these agents' use. Dietary omega-3 supplementation and oxytocin have garnered growing interest among researchers because of promising findings in terms of beneficial effects, in particular on the symptom domain of anger (Bozzatello *et al.* 2020).

Although some studies have suggested a role for opiate antagonists in the treatment of dissociative symptoms and flashbacks in BPD (Bohus *et al.* 1999; Griengl *et al.* 2001), other trials have not demonstrated any benefit of opioid antagonist treatment for acute symptoms of tension and dissociation in BPD (Philipsen *et al.* 2004).

Another neuropeptide system that has received increased attention for drug intervention in the treatment of interpersonal dysfunction is the oxytocin system. Oxytocin is associated with empathic processing and affiliative bonding and has been shown to have attenuating effects on the hypothalamic-pituitary-adrenal axis and the autonomic nervous system. Oxytocin deficits have been linked to attachment insecurity and separation distress, and oxytocin plays a role in the mediation of social cues, trust, and prosocial behavior (Bartz and Hollander 2006). Lower cerebrospinal fluid levels of oxytocin have been found in women with a history of childhood abuse or neglect (Heim *et al.* 2009), and early experimental studies suggested a role for the oxytocin system in attenuating emotional and hormonal responses to stress in BPD (Simeon *et al.* 2011).

Individuals with BPD have been found to lack psychophysiological and amygdala indicators of habituation to repeated interpersonal affective stimuli of positive or negative valence (Hazlett *et al.* 2012). Working through interpersonal experiences may be difficult for BPD patients, and adjunctive medication treatment that targets the capacity for habituation may optimize overall treatment efficacy. Habituation, a process dependent on neuroplasticity and changes in receptor density, is fundamentally affected by glutamatergic *N*-methyl-D-aspartate signaling, which suggests a role for glutamatergic medications in improving the affective, impulsive, interpersonal, and cognitive symptoms of BPD. Enhanced learning and psychophysiological habituation modulated by *N*-methyl-D-aspartate signaling could synergize psychopharmacology and psychotherapy, analogous to strategies proposed for PTSD with respect to enhancement of fear extinction and interference of traumatic memory consolidation (Grosjean and Tsai 2007; Ripoll 2013).

Endocannabinoid neurotransmission has been implicated in impulsivity (Pattij and Vanderschuren 2008), depression and suicidality (Vinod and Hungund 2006), and psychosis (Parolaro *et al.* 2010), possibly related to modulation in dopaminergic signaling (Fitzgerald *et al.* 2012). Both BPD and complex PTSD are powerfully associated with the experience of interpersonal violence during childhood and adolescence. These disorders frequently co-occur and often result in pervasive problems in emotion regulation and pain perception, processes that involve the endocannabinoid system. A study investigated serum levels of the endocannabinoids anandamide and 2-arachidonoylglycerol and related fatty acid ethanolamides in BPD patients, PTSD patients, and healthy control subjects. Significant alterations were found for both endocannabinoids in BPD and for the fatty acid ethanolamide oleoylethanolamide in PTSD, which suggests respective links to these disorders (Schaefer *et al.* 2014).

There is evidence that cyclical hormone changes (e.g., higher progesterone levels in the luteal phase, estrogen fluctuations at ovulation and in the luteal phase) may affect the expression of BPD features among at-risk women (Eisenlohr-Moul *et al.* 2015). Finally, altered levels of inflammatory cytokines such as interleukin-6 (Coccaro *et al.* 2015), prolactin (Atmaca *et al.* 2015b), *N*-acetylaspartate (Atmaca *et al.* 2015a), and cortisol (Rausch *et al.* 2015) have been linked with BPD and suggest putative neurobiochemical targets for future drug research.

An individualized, tailored pharmacotherapy for BPD with the fewest medications needed to target the prominent symptom clusters could improve relevant aspects of the clinical picture. However, no medication is indicated to treat the global psychopathology of this personality disorder. Polypharmacy is still common in clinical practice. It is not supported by data and should be avoided or strongly limited. At the moment, pharmacotherapy alone cannot manage a complex, severe, impairing condition such as BPD. Several core symptom domains, such as fears of abandonment, chronic feelings of emptiness, and identity disturbances, are refractory to pharmacotherapy. They could be the focus of specific psychotherapies or combined therapies. According to available findings, psychotherapy appropriately adapted for severe personality disorders or combined with selected mood stabilizers or new antipsychotics appears to be the most promising therapeutic tool for treating BPD patients (Bozzatello *et al.* 2020).

Conclusions and Treatment Guidelines for Cluster B Personality Disorders

In summary, several open and controlled pharmacological treatment trials of BPD have been conducted. Interpretation of the findings is somewhat complicated by the diversity of patient presentations at treatment entry, including inpatient or outpatient status; overall severity of baseline pathology; presence of comorbid personality disorders; presence or absence of major depressive disorder, including atypical symptoms; emphasis on varying symptomatology, such as psychoticism or impulsive aggression; and use of a wide range of outcome measures. In addition, some of the core features of the disorder, such as identity diffusion, interpersonal vicissitudes, and primitive defensive structure, were never examined, and therefore the assumption that these features are less responsive to medication has not been proven empirically. On the basis of the existent algorithms in the literature, modified according to the results of the latest medication trials, we propose a medication treatment approach for BPD (Table 56-4).

TABLE 56-4. **Psychopharmacological treatment guidelines for borderline personality disorder**

If the most prominent symptoms are depression, interpersonal sensitivity, and impulsivity and aggression:

1. Start with a selective serotonin reuptake inhibitor (SSRI) (or related antidepressant).
2. *If good response*, maintain.
   If partial response, add a mood stabilizer.
   If no response, switch to a different mood stabilizer.
3. *If significant residual anger, anxiety, or dyscontrol*, add an atypical antipsychotic.

If the most prominent symptoms are mood lability, impulsivity and aggression, and family history of bipolar spectrum:

1. Start with a mood stabilizer (valproate; carbamazepine or lithium as alternatives).
2. *If good response*, maintain.
   If partial response, add a second mood stabilizer.
   If no response, switch to a different mood stabilizer.
3. *If significant residual anger, anxiety, or dyscontrol*, add an atypical antipsychotic.

If the most prominent symptoms are paranoia, psychoticism, hostility, and overwhelming anxiety:

1. Start with an atypical antipsychotic (olanzapine and risperidone are the most studied).
2. *If good response*, maintain.
   If partial response, add an SSRI or mood stabilizer.
   If no response and minimal mood symptoms, switch to a typical antipsychotic.

In almost all Cluster B personality disorder trials, BPD has been the primary focus. Although some of these trials, mentioned individually in the overview above, included mixed samples of Cluster B participants, they did not present separate analyses for non-BPD diagnoses. Therefore, the general principle to follow in treating Cluster B disorders other than BPD would be to target symptom clusters with medications as per the guidelines developed for BPD (see Table 56-4). In general, narcissistic and histrionic personality disorders are not characterized by the severe mood lability or impulse dyscontrol seen in BPD, but for individuals in whom such features are more prominent or problematic, medication trials can be attempted.

In regard to antisocial personality disorder, the general treatment guideline is that individuals whose symptoms meet full criteria for the disorder are generally treatment noncompliant and nonresponsive. Although there have been a multitude of interventions tested in the past, an appropriate algorithm fails to exist today. Literature suggests that early treatment of conduct disorder in children is the least costly and most effective treatment for antisocial behavior (Frick 2016). Very few pharmacological studies have focused on patients with antisocial personality disorder (Coccaro 1993). Early trials suggested a role for lithium in reducing markers of antisocial behavior, including rule infractions and impulsive-aggressive behavior, among incarcerated males (Wickham and Reed 1987).

Studies of phenytoin 300 mg/day among prisoners and outpatients also showed some benefit for impulsive (but not premeditated) behaviors as well as reduced measures of anxiety and depression (Stanford *et al.* 2001). Finally, there is some evidence of benefit from nortriptyline (25-75 mg/day) and bromocriptine (15 mg/day) (Powell *et al.* 1995) in reducing alcohol abuse among individuals with antisocial personality disorder, a significant finding in light of the fact

that men with antisocial personality disorder have been found to be three to five times more likely than those without the disorder to abuse alcohol and illicit drugs (Robins and Price 1991).

More recently, a report on four antisocial personality disorder inpatients in a maximum-security facility found decreases in impulsivity, hostility, aggressiveness, irritability, and rage reactions with quetiapine treatment at dosages of 600-800 mg/day (Walker *et al.* 2003). In general, patients with BPD who have some antisocial traits are more responsive to medication treatment than are purely antisocial patients. Studies with the mood stabilizer valproate suggested that individuals with antisocial personality disorder were less responsive to the pharmacotherapy than were subjects with other Cluster B personality disorders (Hollander *et al.* 2003). It also has been found, however, that BPD patients are significantly more likely than antisocial personality disorder patients to have received adequate medication trials with anxiolytics and antidepressants (Zanarini *et al.* 1988).

Pharmacotherapy for Cluster A Personality Disorders

Despite the impact that a Cluster A personality disorder may have on an individual, limited research is available regarding the pharmacological treatment of this disorder. In general, patients with a Cluster A personality disorder tend to isolate and may not readily seek medical attention. Therefore, they may not be easily recruited into research studies (Koch *et al.* 2016). The main symptoms of Cluster A personality disorders--cognitive and perceptual distortions--are reminiscent of both the positive and negative symptoms of schizophrenia, and dopaminergic dysregulation has been postulated to underlie these symptoms (Siever and Davis 1991). Schizotypal personality disorder (SztPD) is by far the most extensively investigated disorder of the cluster in terms of biological underpinnings (Siever 1985; Siever *et al.* 1990), relation to DSM-IV Axis I as a schizophrenia spectrum disorder (Asarnow *et al.* 2001; Kendler *et al.* 1994), and pharmacological treatment trials. Similar to schizophrenia patients, patients with SztPD often demonstrate cognitive processing deficits, structural functioning abnormalities, and other physiological abnormalities (McClure *et al.* 2007). Some studies have reported greater preservation of frontal volume in patients with SztPD (Siever and Davis 2004) compared with patients with schizophrenia. Functional MRI data point to abnormal caudate volumes in SztPD patients with associated cognitive deficits in working memory, implicating striatum dysfunction, and associated abnormalities in cortical-subcortical circuits may play a key role in disorders of cognition and behavior such as SztPD (Levitt *et al.* 2004).

Serban and Siegel (1984) treated a sample of patients, one-third of whom had SztPD and one-third of whom had SztPD and BPD, with either thiothixene or haloperidol without placebo and found marked improvement in psychotic spectrum symptoms. Goldberg *et al.* (1986) treated a sample of outpatients with BPD and/or SztPD with thiothixene or placebo and found a significant improvement in psychotic symptoms with thiothixene that was more pronounced in the patients with SztPD. Soloff *et al.* (1986, 1989), in a sample containing a sizable proportion of patients with combined SztPD and BPD, found haloperidol to be superior to placebo in the treatment of schizotypal symptoms but failed to replicate this finding in a later study (Soloff *et al.* 1993), possibly because of the lower severity of symptoms in the later study.

Schulz *et al.* (1999) reported improvement in psychotic symptoms in a small group of patients who received olanzapine, most of whom had SztPD that was comorbid with BPD. There is one published randomized, placebo-controlled trial of an atypical antipsychotic (risperidone 0.25-2.0 mg/day) focusing exclusively on SztPD, and it found risperidone to be significantly more efficacious than placebo (Koenigsberg *et al.* 2003).

The evidence for the use of antidepressants in the treatment of SztPD symptoms is weak and at times contradictory, with only a few open-label studies demonstrating some improvement in impulsive aggression, self-injurious behaviors, and depressive and psychotic symptoms with the SSRI fluoxetine (Coccaro and Kavoussi 1997; Markovitz *et al.* 1991) and other studies showing detrimental effects (worsening of hostility and paranoia) with the TCA amitriptyline (Soloff *et al.* 1986, 1989).

Randomized controlled trials have shown improved cognitive performance on neuropsychological tasks with pergolide, a dopaminergic agonist active at both the dopamine D_1 and D_2 receptors (McClure *et al.* 2010), and the noradrenergic a_{2A} agonist guanfacine (McClure *et al.* 2007). Research on the neurobiological substrates of social cognitive dysfunction (empathic deficits, relational paranoia, and social isolation in SztPD) may provide future targets for pharmacotherapeutic intervention.

The use of olanzapine, risperidone, haloperidol, fluoxetine, and thiothixene has yielded beneficial results in patients with SztPD; however, treatment with such agents should be considered on a case-by-case basis. A single case series of treatment for paranoid personality disorder in Denmark found no conclusive results to guide future treatment recommendations beyond the tentative conclusion that an antipsychotic may be beneficial. Similarly, because of the complete lack of evidence for schizoid personality disorder, no recommendation for pharmacotherapy treatment can be offered at this time. In conclusion, most of the literature analyzed in this chapter presents theoretical ideas of what may constitute the neurobiological factors of personality and what treatments may address these aspects. Further research is needed to evaluate specific pharmacological treatment of the Cluster A personality disorders. At this time, treatment with pharmacological agents is based on theory rather than evidence (Koch *et al.* 2016).

Pharmacotherapy for Cluster C Personality Disorders

Anxiety and behavioral inhibition are the main symptoms that characterize individuals with Cluster C personality disorders, although the focus of the anxiety varies across disorders. The anxiety centers on social interaction in avoidant personality disorder, need for control of uncertainty in obsessive-compulsive personality disorder, and conflicts surrounding autonomy in dependent personality disorder.

Limited data suggest a role for the MAOI phenelzine (Deltito and Perugi 1986; Liebowitz *et al.* 1988) and the SSRI fluoxetine (Deltito and Stam 1989) in the treatment of avoidant personality disorder. However, in all of these studies, most, if not all, of

the avoidant subjects had comorbid DSM-III (American Psychiatric Association 1980) social phobia (DSM-5 social anxiety disorder), and the criteria used to differentiate the two conditions and their medication response were not clearly defined. In a more systematic approach, Reich *et al.* (1989)

openly treated 14 patients with DSM-III-R (American Psychiatric Association 1987) social phobia with alprazolam for 8 weeks at a mean daily dose of 3 mg and specifically measured treatment response in nine avoidant personality traits on the basis of DSM-III-R diagnostic criteria for avoidant personality disorder. Six of the nine avoidant traits showed significant improvement during treatment, correlating with a change in subjective anxiety and disability.

Greve and Adams (2002) reported anecdotal evidence for the anticonvulsant carbamazepine in the treatment of irritability and hostility associated with obsessive-compulsive personality disorder. Although overlap with OCD was suggested by previous findings of a familial spectrum of OCD and obsessive-compulsive personality disorder (Samuels *et al.* 2000) and the clinical observation that both disorders involve compulsive behaviors, more recent data are emerging that support the separation of the two as distinct clinical entities, differentiable on the basis of obsessions in OCD versus excessive capacity to delay reward in obsessive-compulsive personality disorder (Pinto *et al.* 2014).

Conclusion

In this chapter we reviewed the pharmacological treatment of personality disorders, providing a conceptual framework, highlighting methodological limitations, and summarizing medication treatment trials to date. Almost all of these trials have focused on symptom clusters, such as psychoticism, impulsivity, hostility/aggression, mood instability, and anxiety/inhibition. This focus is consistent with the growing conceptualization of personality disorders as syndromes of overlapping traits arising from a complex interaction between genetic determinants and developmental processes, influenced by adverse life events, with the primary manifestations of the disorders represented as difficulties with interpersonal relationships. The translation of current research into robust clinical recommendations for the treatment of personality disorders has been hampered by a number of methodological limitations, including the heterogeneity of study populations, selective attention to BPD, and diversity in outcome measures. Despite these limitations, there is sufficient evidence to suggest a role for medications as an adjunctive treatment for symptom reduction, functional improvement, and overall adaptation for personality disorders. Progress in our understanding of the neurobiological underpinnings of personality and their component dimensions will help guide the development of better models of personality and its disordered forms, thereby providing a basis for rational pharmacotherapy to complement psychosocial interventions.

CHAPTER 57

Treatment of Eating Disorders

W. Stewart Agras, M.D.

Anorexia nervosa (AN), bulimia nervosa (BN), and binge-eating disorder (BED) have a combined prevalence of 3%-6%, given the diagnostic changes in DSM-5 (American Psychiatric Association 2013; Hudson *et al.* 2007; Mond 2013). About 10% of all cases of AN and BN are in males, with the proportion rising to about 30% for BED in clinical samples. Because much comorbid psychopathology is associated with each of these disorders, including current major depressive disorder in about 25% of cases, the treatment plan must take such disorders into account. At this point only two medications are approved by the FDA for the treatment of eating disorders: fluoxetine for BN and lisdexamfetamine (LDX) for BED. There are no approved medications for the treatment of AN.

Because there are several evidence-based psychotherapies for BN and BED, it is important to consider the relative efficacy of medication and psychotherapy in these disorders and whether adding either one to the other is effective. Hence, in the last section on each disorder I review this issue.

Bulimia Nervosa

BN usually begins in adolescence or early adulthood, with a prodromal period characterized by dissatisfaction with body shape and a fear of becoming overweight, followed by dietary restriction and weight loss.

Sooner or later, periods of dietary restriction are followed by episodes of binge eating experienced as a loss of control over food intake. Ultimately, the individual discovers purging, usually in the form of self-induced vomiting, with or without laxative or diuretic use, excessive exercise, or (less commonly) fasting, and in rare cases in the form of chewing food and spitting it out. Medical complications of BN include potassium depletion and other electrolyte disturbances, which combined with low weight may lead to cardiovascular complications and death (Gibson *et al.* 2019; Westmoreland *et al.* 2016). Other complications include esophageal bleeding, dental caries, salivary gland enlargement, and exercise injuries. Some 20% of patients with BN have a history of AN.

Antidepressants

Fluoxetine

Three seminal studies outlined the short-, medium-, and long-term effectiveness of fluoxetine. In a placebo-controlled trial 387 women with BN were randomly assigned to either fluoxetine (20 mg/day or 60 mg/day) or placebo for 8 weeks following a 1-week placebo washout (Fluoxetine Bulimia Nervosa Collaborative Study Group 1992). A dosage of 60 mg/day was found to be significantly more effective than either 20 mg/day or placebo in reducing binge eating and purging, with 20 mg/day showing an intermediate effect and being superior to placebo in reducing purging but not binge eating. A modest but statistically significant difference in weight loss was seen between women taking fluoxetine 60 mg/day (1.6 kg/day) and those taking placebo (0.0 kg/day). Indices of eating disorder psychopathology, such as body dissatisfaction, also improved at the 60 mg/day dosage. In a different study, 16 weeks in duration, 398 subjects with BN were randomly assigned to either fluoxetine 60 mg/day or placebo (Goldstein *et al.* 1995). A larger percentage of women in the fluoxetine group than in the placebo group reduced their vomiting by more than 50%

(53.1% vs. 35%). The difference for stopping vomiting was also statistically significant between the fluoxetine and placebo groups (19% vs. 12%).

Little is known about the long-term effectiveness of fluoxetine. In a study of this issue, 147 women with BN who had decreased their vomiting by at least 50% while taking 60 mg/day of fluoxetine over an 8-week period were randomly allocated to continue medication or to be switched to placebo (Romano *et al.* 2002). A survival analysis found that the group receiving active medication experienced a longer time to relapse than did the placebo group. Estimated relapse rates for the fluoxetine group at 3, 6, and 12 months were 19%, 29%, and 33%. It should be noted, however, that at the 12-month follow-up, 83% of the fluoxetine group and 92% of the placebo group had relapsed or dropped out. Side effects were reported at higher rates by those receiving fluoxetine compared with placebo. Side effects in these trials were insomnia, nausea, dizziness, sweating, and decreased libido. Hence, the safety profile is similar to that found in the treatment of depression.

Other Antidepressants

Fluoxetine should be the pharmacological agent of choice for the treatment of BN. However, most antidepressants, used off-label, appear to be effective at antidepressant dosages. Little is known about longer-term outcomes with antidepressants other than fluoxetine. One study compared different lengths of desipramine treatment for BN. Participants with BN treated for 16 weeks relapsed to pretreatment levels of binge eating when desipramine was withdrawn. However, those treated for 24 weeks maintained remission after withdrawal and at 1-year follow-up (Agras *et al.* 1992, 1994). This study suggests that patients who respond to antidepressant treatment should be given a minimum trial of 6 months on medication.

An interesting study involving 77 BN patients (Walsh *et al.* 2006b) examined the rate of decline in symptoms of bulimia with desipramine. The authors found that patients unlikely to respond to the antidepressant could be reliably identified after 2 weeks of treatment. This finding was replicated in a combined dataset ($N = 785$) from two controlled trials (Sysko *et al.* 2010). Patients who did not reduce binge eating or vomiting by 60% by week 2 of treatment were unlikely to respond to fluoxetine. Early identification of poor responders allows for the deployment of different approaches to treatment, for example, a different antidepressant or cognitive-behavioral therapy (CBT). Side effects and reasons for discontinuing the various medications are similar to those observed in the treatment of depression. However, a study of bupropion found that a higher-than-expected proportion of patients with bulimia developed grand mal seizures (Horne *et al.* 1988). The authors concluded that bupropion should not be used for the treatment of BN.

Anticonvulsants

Topiramate

The rationale for considering topiramate as a treatment for BN is that patients with epilepsy were found to experience appetite reduction and weight loss on this medication. In one study (Hoopes *et al.* 2003), patients whose symptoms met criteria for DSM-IV-TR BN (American Psychiatric Association 2000) were allocated at random to treatment with either topiramate ($n = 35$) or placebo ($n = 34$) over a 10-week period. Twenty-two (63%) of those in the topiramate group completed the trial, and topiramate was statistically superior at reducing binge eating and purging, with 22% of completers in remission at the end of treatment. Other studies have shown similar findings, with greater efficacy of topiramate over placebo in percent reductions in binge eating and purging, reductions in body dissatisfaction and drive for thinness, and reductions in anxiety and depression (Hedges *et al.* 2003; Nickel *et al.* 2005). The mean dose of topiramate in these studies was 100 mg/day (range 25-400 mg/day). Side effects commonly seen with topiramate are drowsiness, fatigue, distractibility, insomnia, and cognitive blunting.

Combined Treatment

CBT for BN developed in parallel with the use of antidepressants. On the basis of the research literature, CBT is considered the first-line treatment for BN because it appears to be more effective than antidepressant medication and other psychotherapies such as interpersonal psychotherapy (Linardon *et al.* 2017; National Institute for Health and Care Excellence 2017; Slade *et al.* 2018). The existence of two different and effective treatments, antidepressant medications and CBT, naturally led to the question of whether the combination of these treatments would be more effective than either treatment alone. A meta-analysis of controlled studies examining this question (Reas and Grilo 2021) found no advantage for combining treatments in 10 of 12 studies. Hence, in the absence of patient preference for medication over psychotherapy, CBT should be the treatment of choice for BN, followed by medication if there is a poor response to psychotherapy.

Binge-Eating Disorder

The principal features of BED are episodes of binge eating followed by marked distress. Purging and other compensatory behaviors do not occur in this condition, although about 10% of patients with BED have a history of BN.

Between 1% and 3% of women in the general population have symptoms that meet criteria for BED. The ratio of women to men with BED is approximately 3:2, the highest rate for men of any eating disorder. Although obesity is not a requirement for a diagnosis of BED, there is a substantial overlap between BED and obesity. Studies have shown that about one-quarter of obese individuals have symptoms that meet criteria for BED and that the prevalence of binge eating increases as BMI increases (Marcus *et al.* 1985; Spitzer *et al.* 1993; Telch *et al.* 1988). Moreover, BED is associated with comorbid psychopathology similar to that seen in BN.

Lisdexamfetamine

LDX, a prodrug that has L-lysine conjugated to dextroamphetamine, is FDA approved for the treatment of ADHD in both children and adults and was approved in 2015 for the treatment of moderate to severe BED in adults (Bello and Yeomans 2018). Commonly reported side effects include dry mouth, decreased appetite, insomnia, and headache. Because LDX is converted to amphetamine, it has addictive potential; hence, the U.S. Drug Enforcement Agency has classified LDX as a Schedule II controlled medication. Patients with BED should be carefully screened for past drug or alcohol overuse.

A series of randomized double-blind, controlled studies demonstrated the safety and efficacy of LDX in both the short and longer term, clarified dosage levels, and investigated the course of improvement in binge eating. In the first study, 514 adults whose symptoms met criteria for BED were randomly allocated to dosages of 30 mg/day, 50 mg/day, or 70 mg/day or to placebo for 11 weeks (McElroy *et al.* 2015). The primary outcome, change in the number of binge-eating days per week, significantly favored LDX over placebo except for the 30 mg/day dosage, with no difference between the two higher dosages. Cessation of binge eating over a 4-week period occurred in 21.3% of participants in the placebo group compared with 34.9% of individuals receiving LDX at 30 mg/day, 42.2% at 50 mg/day, and 50% at 70 mg/day. Weight loss was 0.1 kg in the placebo group compared with 4.3 kg across all three dosages of LDX. There were no serious adverse events.

Following this pivotal study, two parallel randomized, placebo-controlled studies enrolled a total of 386 participants whose symptoms met criteria for BED (McElroy *et al.* 2016). Each study included multiple sites (50 and 43). The dosage of LDX, either 50 mg/day or 70 mg/day, was optimized for each participant depending on tolerability for a duration of 12 weeks. In both studies, those randomly allocated to LDX reduced their binge eating and weight significantly more than those in the placebo groups. Abstinence rates for the two studies combined were 13.6% for the placebo groups and 38.1% for the LDX groups. The results were similar in both studies, replicating the results of the previous Phase II study. McElroy *et al.* (2017) further examined the rate of improvement in binge eating at weekly intervals in the placebo and LDX groups. The frequency of binge eating, abstinence from binge eating, and percent change in body weight differed between placebo and LDX after 1 week of treatment and continued to increase, stabilizing around week 9. Hence, there is a rapid therapeutic response to LDX both for reduction in and cessation of binge eating and for weight loss.

A multinational, multisite study further examined the longer-term effectiveness of LDX (Hudson *et al.* 2017). A total of 411 participants whose symptoms met criteria for BED began open-label treatment with LDX. The dosage of LDX was individually optimized

for each participant at either 50 mg/day or 70 mg/day. At the end of 12 weeks on LDX, 275 participants who remained in the study and who binged once or less per week were randomly allocated to placebo or to LDX to examine the rate of relapse over a 6-month period. Relapse was defined as > 2 binge-eating episodes a week for 2 consecutive weeks. In the primary analysis, the time to relapse was significantly longer in the LDX group than in the placebo group, with 5.1% of participants in the LDX group relapsing compared with 34.4% in the placebo group. Only 20% of those receiving LDX in the randomized phase did not complete the study.

Antidepressants

Double-blind, placebo-controlled studies suggest that antidepressants are at least as useful in the treatment of BED as they are in the treatment of BN. Early placebo-controlled studies found desipramine to be effective in reducing binge eating, with an abstinence rate of 60% (McCann and Agras 1990). Studies of selective serotonin reuptake inhibitors have suggested moderate efficacy, with overall remission rates of approximately 40% compared with 20% for placebo (Appolinario and McElroy 2004; McElroy *et al.* 2010). Most studies showed some degree of weight loss, which for the most part was not clinically significant.

Anticonvulsants

Topiramate

Anticonvulsants such as topiramate also appear useful in the treatment of BED (McElroy *et al.* 2009). The mechanism of action of anticonvulsants in BED is unclear but is likely a combination of appetite suppression and satiety enhancement via delayed gastric emptying. A 16-week double-blind multisite study in which 394 participants with BED were allocated at random to receive either topiramate or placebo provided evidence for the efficacy of topiramate (McElroy *et al.* 2007). The median dosage of topiramate was 300 mg/day. Dropout rates were equivalent between the groups (29% topiramate, 30% placebo). Fifty-eight percent of participants in the topiramate group and 29% of those in the placebo group were in remission at the end of the study period. There was a mean weight loss of 4.5 kg in the topiramate group versus a small weight gain in the placebo group. The most common side effects specific to topiramate were paresthesia and difficulty concentrating. Hence, topiramate leads to a reasonable rate of remission of the eating disorder combined with substantial and clinically meaningful weight loss.

Medication Combinations

Phentermine/Topiramate

The combination of phentermine and topiramate was approved by the FDA for the treatment of obesity in 2012. The rationale for combining the two medications was to increase both effectiveness and tolerability. The improved tolerability may be due to the opposing side effects of the two medications. The stimulant effects of phentermine may reduce the sedative and cognitive effects of topiramate, leading to greater tolerability and reduced dropout rates. Lower dosages of each medication may also reduce side effects. Only one study of the combination for treating an eating disorder

has been reported to date. Using a crossover design, Safer *et al.* (2020) compared the combination of phentermine and topiramate with placebo in

22 participants (18 whose symptoms met DSM-5 criteria for BED and 4 whose symptoms met criteria for BN). Abstinence rates (no binge eating in a 4-week period) were 63.6% for the combined medication and 9.1% for placebo, with a weight loss of 6.5 kg in the medication group compared with a slight gain in weight for the placebo group, rates roughly comparable to those obtained in studies of LDX. These results suggest that the combination of phentermine and topiramate is likely to be effective in the treatment of BED. No serious adverse effects were noted in this study, and cardiovascular effects in the medication and placebo groups were comparable. The combination of phentermine and topiramate appears promising and merits further larger-scale studies.

Naltrexone/Bupropion

Although there is clear evidence that the combination of naltrexone and bupropion leads to significant weight loss in the treatment of obesity, there has been only one small-scale controlled study of the effectiveness of this combination in treating BED (Grilo *et al.* 2021). Twenty-two participants were randomly allocated to receive either a fixed daily dosage of a combination medication (naltrexone 50 mg, bupropion extended release 300 mg) or placebo for 12 weeks with a 6-month follow-up. Naltrexone/bupropion was well tolerated, and there were substantial reductions from baseline in binge eating and eating disorder psychopathology, but there were no significant differences in clinical outcomes between patients receiving the medication and patients receiving placebo. Weight reductions favored the naltrexone/bupropion combination. Larger trials of this combination are needed.

Combined Treatment Modalities

BED presents three problems to the clinician: binge eating; overweight; and comorbid psychopathology, in particular depression and anxiety disorders. Hence, comprehensive treatment should address all of these problems. CBT is widely regarded as the treatment of choice for BED (National Institute for Health and Care Excellence 2017), followed by interpersonal psychotherapy, although weight loss is minimal with either psychotherapy; hence, it may be necessary to use medication to treat the residual overweight. Among the medications available for the treatment of obesity, the largest mean weight losses (minus placebo response) have been for naltrexone/bupropion (6.1 kg), phentermine (6.4 kg), and phentermine/topiramate (8.7 kg) (Dragano *et al.* 2020). There are few direct comparisons of psychotherapy and medication for the treatment of BED. In a meta-analysis of treatments aimed at reducing binge eating compared with placebo or no treatment, there was an advantage for CBT (RR = 4.95) compared with LDX (RR = 2.61). However, there has been no direct comparison of LDX and CBT or of their combination. For patients who prefer medication, current evidence suggests that LDX is the most effective pharmacological agent reducing both binge eating and weight.

Anorexia Nervosa

AN is characterized by dietary restriction followed by marked weight loss, intense fear of gaining weight, and disturbance in the experience of body shape (e.g., feeling fat despite marked weight loss). It is the most lethal psychiatric disorder. A meta-analysis of 41 cohorts from peer-reviewed studies published between 1966 and 2010 found that AN patients were 5.2 times more likely to die prematurely than females in the general population and 18.1 times more likely to die by suicide (Keshaviah *et al.* 2014). Because of the disabling nature and chronicity of the condition and the lack of evidence-based treatments for the persistent form of the disorder early identification and treatment of the disorder are essential.

Controlled pharmacological studies in both adolescents and adults with AN have generally shown a lack of efficacy (Blanchet *et al.* 2019; Suarez-Pinilla *et al.* 2015). However, many of the studies are underpowered or have very high dropout rates, which makes it difficult to draw firm conclusions regarding effectiveness.

Antipsychotics

Most studies of antipsychotic agents in the treatment of AN, including chlorpromazine, pimozide, sulpiride, olanzapine, and risperidone, have shown no evidence of efficacy for weight gain (Blanchet *et al.* 2019). However, in a multisite trial 152 outpatients with AN were randomly assigned to olanzapine or placebo for 16 weeks (Attia *et al.* 2019). The primary outcomes were rate of weight gain and obsessionality, with secondary outcomes of improvement in eating disorder and other psychopathology. Almost half the participants had dropped out by week 16, with no difference between the two randomized groups. However, those receiving olanzapine gained weight more rapidly than those receiving placebo, with a medium effect size of 0.63. There were no differences between the two groups for obsessionality, anxiety, or eating disorder psychopathology. Olanzapine was well tolerated, with no difference in rates of medication discontinuation between medication and placebo. The results of this study suggest that the use of olanzapine by patients with AN confers a modest benefit for weight gain. The authors suggested that olanzapine may be a useful adjunct to psychological treatment.

Antidepressants

There is little evidence that antidepressants are effective when used in either an inpatient treatment setting focusing on weight gain or an outpatient setting focusing on weight maintenance (Blanchet *et al.* 2019; Mitchell *et al.* 2013). An inpatient study found that fluoxetine was not effective in hospitalized patients with AN (Attia *et al.* 1998). In that study, 31 women hospitalized with AN participated in a 7-week randomized, double-blind, placebo-controlled trial of fluoxetine at a mean dosage of 56 mg/day. Four patients in the fluoxetine group and four patients in the placebo group terminated the trial early. Although all patients in the study showed improvement, no significant differences were seen between those who received active medication and those who received placebo. In addition, there was no apparent effect of medication on depression or on symptoms of obsession. This study suggests that fluoxetine has no effect over and above that of an inpatient program and adds to the consistent failure in the literature to show a beneficial effect of antidepressant medication during the period of weight regain.

Despite promising findings in an earlier small-scale outpatient study (Kaye *et al.* 2001), a double-blind, placebo-controlled trial of 93 adult outpatients found no benefit for fluoxetine in either promoting weight maintenance or prolonging time to relapse (Walsh *et al.* 2006a). As is usual in this population, a large proportion of patients

dropped out or terminated treatment early (51% of fluoxetine-treated and 63% of placebo-treated patients). A fairly high proportion of patients were dissatisfied with treatment. Hence, the use of fluoxetine is not indicated in the treatment of AN except to treat comorbid psychopathology.

Combined Treatment

There is no evidence-based psychotherapeutic treatment for persistent AN; CBT, psychodynamic psychotherapy, and medical care plus supportive psychotherapy are all effective in producing modest weight gain, but there is little evidence that one treatment is either superior or specific (Wonderlich *et al.* 2020). Hence, no psychotherapy has specific effects in the treatment of persistent AN, and there is no evidence that combining psychotherapy and medication is effective.

A specific family therapy for adolescents with AN (family-based treatment) that helps parents take charge of their child's eating is effective in both the short and long term, with about 50% of adolescent patients with anorexia recovered both at the end of treatment and at follow-up (Lock 2019). Moreover, it is more effective than other psychotherapies with which it has been compared. No pharmacological agent has shown benefit for this group of patients; therefore, for adolescent AN, family therapy in general and family-based treatment in particular are the only evidence-based treatments (Hay *et al.* 2014; Resmark *et al.* 2019).

Conclusion

It is perhaps surprising that there are so few effective pharmacological agents for the treatment of eating disorders. The place of psychopharmacological agents in the treatment of BN has been well worked out. Treatment with sequential trials of different antidepressants should result in abstinence rates of about 40%. The addition of CBT enhances the effectiveness of antidepressants. The most effective pharmacological agent for the treatment of BED appears to be LDX because it effectively reduces both binge eating and weight. In the case of AN, there is now evidence from one controlled trial that olanzapine may be helpful for weight gain. No other pharmacological agents are helpful in either inpatient or outpatient treatment of adult patients except to treat comorbid psychiatric disorders. There is insufficient information regarding adolescent AN to provide guidance regarding the use of medication at this point.

CHAPTER 58

Treatment of Insomnia

Andrew D. Krystal, M.D., M.S.

Disturbances of sleep occur at some point in the life of essentially everyone. However, the presence of a clinically significant insomnia disorder requires that the sleep disturbance meet a specific set of criteria: 1) There is a complaint of difficulty falling asleep or staying asleep, 2) this complaint is associated with clinically significant distress and/or daytime functional impairment, 3) these difficulties occur despite an adequate opportunity for sleep, and 4) the sleep disturbance is present for three or more nights per week for at least 3 months (American Academy of Sleep Medicine 2014; American Psychiatric Association 2013; Krystal 2007).

Available research suggests that insomnia disorder has a population prevalence of approximately 10% and is associated with impairments in quality of life; accidents; falls in elderly people; limitations of function; increased risk of hypertension; and increased risk of major depressive disorder, anxiety disorders, suicidality, and substance-related disorders (Avidan *et al.* 2005; Baglioni *et al.* 2011; Bathgate *et al.* 2016; Breslau *et al.* 1996; Ford and Kamerow 1989; Harvey 2008; Johnson *et al.* 2000; Kessler *et al.* 2012; Koski *et al.* 1998; Leger *et al.* 2008; Morin *et al.* 2011; Ohayon 2002; Ohayon and Reynolds 2009; Roth *et al.* 2011; Stone *et al.* 2014; Vgontzas *et al.* 2013; Winsper and Tang 2014). Insomnia disorder most often occurs along with psychiatric and medical conditions (Ford and Kamerow 1989; Sarsour *et al.* 2010). For many years, insomnia, especially when chronic, was assumed to be a symptom of these conditions (National Institutes of Health 1984, 2005). On this basis, directing treatment specifically to chronic insomnia was discouraged. Instead, it was recommended that treatment be administered for the associated medical and psychiatric conditions under the assumption that the insomnia would improve along with the other symptoms of the medical or psychiatric condition (National Institutes of Health 1984, 2005). Over time, the accumulating evidence suggested that this model was fundamentally flawed (Krystal 2015; National Institutes of Health 2005). In approximately 15% of the patients with insomnia who have so-called primary insomnia, no associated condition exists to treat (Edinger *et al.* 2011; Ohayon 1997). Evidence also indicates that treating the associated medical or psychiatric condition often fails to alleviate the insomnia and that insomnia has an adverse effect on the treatment response and course of depression, pain conditions, and anxiety disorders (Krystal 2015; Krystal *et al.* 2012; National Institutes of Health 2005). Further undermining the model that insomnia is invariably a symptom of psychiatric and medical conditions are the data referred to earlier indicating that insomnia is a risk factor for subsequent suicidality and psychiatric and medical conditions (Avidan *et al.* 2005; Baglioni *et al.* 2011; Bathgate *et al.* 2016; Breslau *et al.* 1996; Ford and Kamerow 1989; Harvey 2008; Johnson *et al.* 2000; Kessler *et al.* 2012; Koski *et al.* 1998; Stone *et al.* 2014; Vgontzas *et al.* 2013; Winsper and Tang 2014). These observations have led to a change in the paradigm for insomnia treatment.

It is now appreciated that the relationship between insomnia and associated conditions is complex and often bidirectional and that directing treatment specifically to insomnia is generally warranted whether that insomnia occurs on its own or as a condition comorbid with psychiatric or medical conditions (National Institutes of Health 2005). Two primary types of treatment are available for specifically targeting insomnia disorder: 1) cognitive-behavioral therapy for insomnia, the primary nonpharmacological therapy for insomnia; and 2) pharmacological therapy. A large evidence base supports the efficacy of cognitive-behavioral therapy for insomnia for the treatment of insomnia, including primary insomnia and insomnia occurring with pain and major depressive disorder (Carney et al. 2017; Edinger et al. 2001, 2005; Manber et al. 2016; Morin et al. 2006; National Institutes of Health 2005). Pharmacotherapy, the focus of this chapter, is by far the most commonly administered treatment for insomnia disorder.

In this chapter, I review the neuropharmacology of pharmacological therapies for insomnia and examine their characteristics and clinical application. This information will optimize medication management for insomnia.

Sleep-Wake Pharmacology-- The Basis for Understanding Pharmacological Treatments for Insomnia

The pharmacological systems that regulate sleep-wake function consist of two types: 1) systems that promote sleep and 2) systems that promote wakefulness (Saper *et al.* 2005) (Table 58-1). These systems are mutually inhibitory, such that greater activity in sleep-promoting systems inhibits the wakefulness-promoting systems and vice versa, thereby stabilizing the state of an individual into either sleep or wakefulness. The most important sleep-promoting systems include GABA, galanin, adenosine, and melatonin, whereas the wake-promoting systems include histamine, acetylcholine, norepinephrine, serotonin, dopamine, and hypocretin/orexin (Saper *et al.* 2005). Agents that have therapeutic effects in treating insomnia either enhance the activity of one or more sleep-promoting systems or block the effects of one or more wake-promoting systems (Krystal *et al.* 2013b).

TABLE 58-1. Sleep-wake neurotransmitters (sleep-promoting and wake-promoting)

Key sleep-promoting systems	Key wake-promoting systems
g-Aminobutyric acid	Hypocretin/orexin
Galanin	Norepinephrine
Melatonin	Histamine
	Acetylcholine
	Serotonin
	Dopamine

Although there have long been agents available that differ in which of the sleep-wake systems they affect, it has generally been believed that the pharmacological

mechanism of action of agents used to treat insomnia has no bearing on their clinical effects (Krystal *et al.* 2013b). Instead, clinical effects have been assumed to be determined by dosage and pharmacokinetics (Krystal *et al.* 2013b). The higher the dosage, the greater the clinical sleep-enhancing effect; the higher the dosage and the more rapid the absorption, the sooner the clinical effect occurs; and the higher the dosage and the longer the elimination half-life, the longer the duration of sleep enhancement (Krystal *et al.* 2013b). This model emerged at the time when the pharmacological management of insomnia was dominated by a group of agents--benzodiazepines (e.g., triazolam, temazepam, flurazepam) and nonbenzodiazepines (e.g., zolpidem, zaleplon, eszopiclone)--that had a common mechanism: sleep enhancement via positive allosteric modulation of GABA_A receptors (Krystal 2009; Krystal *et al.* 2013b). Systematic data on clinical effects were essentially available only for these agents, for which the pharmacokinetics/dosage model was largely correct. Their peak effect occurs at the time of peak blood level, the speed of onset of clinical effects is proportional to the rate of absorption, and the duration of effects is proportional to the elimination half-life. However, medications are available for the treatment of insomnia that have a fundamentally different mechanism and specifically block a single wake-promoting system (Krystal *et al.* 2013b). These agents with targeted, less global effects carry the promise of an improved risk-benefit ratio when used by patients with sleep problems that are especially responsive to a particular agent's mechanistic effects. Studies examining the clinical effects of these more targeted medications have only relatively recently been conducted, and they have verified these agents' improved risk-benefit profiles. Their findings have also begun to undermine the prevailing model, in which clinical effects are posited to be driven solely by dosage and pharmacokinetics, with mechanism of action playing no role (Herring *et al.* 2016; Krystal *et al.* 2010, 2011; Michelson *et al.* 2014).

One agent that illustrates this point is doxepin, a highly selective histamine type 1 (H1) receptor antagonist that (at a dose of 3-6 mg) enhances sleep by specifically blocking the wake-promoting effects of histamine (Krystal *et al.* 2010, 2011, 2013b). The peak therapeutic effect does not occur at peak blood level, which is approximately 3-4 hours after ingestion, but instead occurs at the end of the night about 4 hours later (Krystal *et al.* 2010, 2011, 2013b). According to the model in which pharmacokinetics and dosage dominate clinical effects, this would not be possible, and a drug with a peak effect at the end of the night would be useless because it would cause prohibitive morning sedation or impairment (Krystal *et al.* 2013b). Because clinical effects should be proportional to blood level, and blood level only decreases incrementally over time, a drug with its biggest effect in hour 8 of an 8-hour night should have effects that are nearly as large in hour 9, the first hour of the day, at which time sleep-enhancing effects are problematic (Krystal *et al.* 2013b). Yet doxepin 3-6 mg has its greatest effects in hour 8 without clinically significant effects during waking 1 hour later (Krystal *et al.* 2010, 2011). This profile of effects is incompatible with a model in which therapeutic effects are dominated by pharmacokinetic factors and indicates that factors other than pharmacokinetics play an important role in determining clinical effects (Krystal *et al.* 2013b). These factors include the specific properties of the pharmacological system(s) modulated by a given drug and activity in other systems that can affect sleep-wake function, which are determined by factors such as time of day, the behavior of the individual taking the medication, and the psychosocial context (e.g., stress, a novel environment, excitement [Krystal *et al.* 2013b]). The relevance of other systems was not apparent during the era when GABA$_A$-positive allosteric modulators dominated insomnia pharmacotherapy, because those agents broadly inhibit brain function, nonspecifically shutting down all of the wake-promoting systems. Agents that specifically inhibit a single wake-promoting system have brought to light how activity in systems that are not inhibited can contribute to clinical effects.

Consider again doxepin 3-6 mg as an example. The clinical effects of specifically blocking the histamine system reflect both the characteristics of the histamine system and the activity in parallel wake-promoting systems. Histamine is under the control of the circadian clock, and its release varies systematically over the 24-hour cycle (Krystal *et al.* 2013b). When its release is minimal, the clinical effects of blocking H$_1$ receptors should be minimal, whereas at times of significant release of histamine, a therapeutic effect can be expected. However, the activity of other sleep-wake-modulating systems that are not inhibited by doxepin 3-6 mg also plays a role. Whether the blockade of H$_1$ receptors manifests in a clinical sleep-enhancing effect will depend on the activity in other wake-promoting systems. If this activity is high, those systems will themselves sustain wakefulness even with significant blockade of H$_1$ receptors (Krystal *et al.* 2013b).

The activity in these parallel wake-promoting systems can be dependent on psychosocial context; for example, in an individual who is stressed or excited, noradrenergic neuronal activity is likely to be high and could maintain wakefulness despite H$_1$ receptor antagonism (Krystal *et al.* 2013b). Another example concerns the effects of time of day. After an individual awakens for the day during the usual waking period, activity in the neuropeptide hypocretin/orexin system is increased and can maintain wakefulness even if H$_1$ receptors are blocked (Krystal *et al.* 2013b). This explains why doxepin 3-6 mg might have its largest effects in hour 8 of an 8-hour night and not have impairing effects after waking: at the end of the night, histamine release is high, and the parallel wake-promoting activity is normally relatively minimal, yet after waking, activity in parallel wake-promoting systems increases and can maintain wakefulness despite the blockade of H$_1$ receptors (Krystal *et al.* 2013b). Thus, to determine the likely clinical effects of a medication, it is necessary to know not only dosage and pharmacokinetic parameters but also the mechanism of action in terms of which pharmacological system(s) it modulates, whether that system is modulated by the circadian rhythm and state (e.g., activity, stress, novelty), and what the circadian and state dependence are of the parallel pharmacological systems that could oppose or enhance clinical effects.

Accordingly, the model that is the basis for the current chapter is that mechanism matters and that three primary factors determine the clinical effects of medications used to treat insomnia: 1) the mechanism of action, 2) drug pharmacokinetics, and 3) dosage. I review the characteristics of the various medications available for the treatment of insomnia organized by pharmacological mechanism of action. This includes reviews of the important drugs that enhance sleep-promoting systems, which consist of benzodiazepines, nonbenzodiazepines, and melatonin receptor agonists, and the important wake-promoting system antagonists, which consist of selective antihistamines, selective hypocretin/orexin receptor antagonists, selective adrenergic receptor antagonists, and nonselective wake-promoting system antagonists.

Pharmacological Treatments for Insomnia

Agents That Improve Sleep by Enhancing Sleep-Promoting Systems

The appendix table at the end of this chapter provides an overview of the properties of medications commonly used to treat insomnia.

$GABA_A$-Positive Allosteric Modulators

Benzodiazepines. Benzodiazepines are a group of medications that are $GABA_A$-positive allosteric modulators and share a chemical structure (Krystal 2009; Minkel and Krystal 2013). The site on the $GABA_A$ receptor complex to which these agents bind is referred to as the *benzodiazepine binding site*. By binding to this site, these agents broadly enhance GABA-mediated inhibition, which inhibits all of the wake-promoting systems and promotes sleep (Sieghart and Sperk 2002).

Benzodiazepines used for the treatment of insomnia. Five agents are indicated for the treatment of insomnia by the FDA: triazolam, flurazepam, temazepam, estazolam, and quazepam (Krystal 2009). Several other agents--clonazepam, alprazolam, and lorazepam--are commonly used to treat insomnia but have approved indications for conditions other than insomnia, such as anxiety and seizures (Krystal 2009).

Clinical therapeutic effects as indicated by available studies. Triazolam, flurazepam, estazolam, quazepam, and temazepam were found to have efficacy for the treatment of both sleep-onset problems and sleep-maintenance difficulty in at least one placebo-controlled trial (Krystal 2009).

Effects on systems other than sleep-wake systems. GABA is the predominant inhibitory neurotransmitter in the brain. For this reason, benzodiazepines, which broadly enhance $GABA_A$-mediated inhibition, can affect many brain systems. Some of the associated effects, including anxiety reduction, myorelaxant, and antiseizure effects, can be therapeutic for some patients (Krystal 2009). Other associated effects represent adverse effects, including cognitive impairment, motor impairment, and abuse potential (Krystal 2009).

Optimal target patient population. Benzodiazepines are best suited for use by those who can benefit from the effects these agents may have on systems other than sleep-wake systems, including those with anxiety or pain problems. Compared with other available agents, these agents also have relatively potent beneficial effects for sleep-onset problems (Krystal 2009). Thus, although the adverse effects of these medications outweigh the beneficial effects for most patients, for some with sleep-onset problems and comorbid conditions, these medications may have the best risk-benefit ratio of the available agents.

Nonbenzodiazepines. The term *nonbenzodiazepine* has been used to describe a set of agents that work by the same mechanism as benzodiazepines, positive allosteric modulation of $GABA_A$ receptors, but do not have the chemical structure of benzodiazepines (Krystal 2009; Minkel and Krystal 2013).

Nonbenzodiazepines used for the treatment of insomnia. Three agents are indicated for the treatment of insomnia by the FDA: zolpidem, zaleplon, and eszopiclone (Krystal 2009). Zolpidem is also available in formulations other than an immediate-release formulation, including an extended-release version and a transoral version that is absorbed through the oral mucosa to a degree.

Clinical therapeutic effects as indicated by available studies. Zolpidem, zaleplon, and eszopiclone were found to have efficacy for the treatment of sleep-onset problems in at least one placebo-controlled trial (Krystal 2009). However, only eszopiclone and the extended-release formulation of zolpidem have been found to have therapeutic effects for sleep-maintenance problems (Krystal *et al.* 2003, 2008a; Walsh *et al.* 2007). Both zaleplon and the transoral formulation of zolpidem have been found to have therapeutic effects for helping people return to sleep after middle-of-the-night awakenings (Roth *et al.* 2013; Zammit *et al.* 2006).

Effects on systems other than sleep-wake systems. Because nonbenzodiazepines are GABA$_A$ allosteric modulators like benzodiazepines, they have the potential to have broad inhibitory effects on brain function. However, some evidence indicates that the clinical effects of nonbenzodiazepines are more limited than those of benzodiazepines (Jia *et al.* 2009; Sanna *et al.* 2002). The clinical effects of benzodiazepines are believed to be mediated by their binding to four types of GABA$_A$ receptors, whereas nonbenzodiazepines bind less broadly to these GABA$_A$ receptors (Jia *et al.* 2009; Sanna *et al.* 2002). Zolpidem and zaleplon bind relatively specifically to GABA$_A$ receptors that are sleep-promoting and are also associated with cognitive and motor impairment, whereas eszopiclone tends to bind to GABA$_A$ receptors that are also associated with sleep enhancement and some degree of psychomotor impairment but have relatively greater myorelaxant, anxiolytic, and possibly antidepressant effects. Clinical evidence for this is that unlike zolpidem, eszopiclone has been found to lead to improvement in anxiety, depression, and pain when combined with the usual therapies for these conditions in placebo-controlled trials (Fava *et al.* 2006, 2009, 2011; Goforth *et al.* 2014; Krystal *et al.* 2007a; Pollack *et al.* 2008).

Optimal target patient population. Nonbenzodiazepines are among the most widely administered insomnia therapies because of their strong effects on sleep onset and the perception that they have a better safety profile than benzodiazepines. In general, nonbenzodiazepines are the treatments of choice for pharmacotherapy of sleep-onset problems. Zolpidem (modified release) and eszopiclone are also agents to consider along with hypocretin/orexin antagonists (see the subsection "Selective Hypocretin/Orexin Receptor Antagonists") for treating problems with sleep maintenance when they co-occur with sleep-onset problems; however, when sleep-maintenance problems occur without sleep-onset difficulty, selective H$_1$ receptor antagonists appear to have a more favorable risk-benefit profile (see "Selective H$_1$ Receptor Antagonists"). Individuals who have intermittent problems with waking up in the middle of the night who are appropriate candidates for using an as-needed rescue medication to help speed the return to sleep are best treated with transoral zolpidem and zaleplon on the basis of available data (Roth *et al.* 2013; Zammit *et al.* 2006). Finally, because only eszopiclone has been found to improve anxiety, depression, and pain outcomes when administered along with the usual first-line treatments for these conditions when they co-occur with insomnia, this medication should be considered as a first-line therapy for patients with insomnia occurring with these conditions (Fava *et al.* 2006, 2009, 2011; Goforth *et al.* 2014; Krystal *et al.* 2007a; Pollack *et al.* 2008).

Melatonin Receptor Agonists

Melatonin receptor agonists have melatonin receptor agonism as their primary clinical effect.

Melatonin receptor agonists used for the treatment of insomnia. Two selective melatonin receptor agonists are available: melatonin, which is available over the counter; and ramelteon, which is available by prescription only and is FDA approved for the treatment of insomnia (Krystal 2009).

Melatonin is released by the pineal gland during the dark period of the circadian cycle (Dubocovich *et al.* 2003). Sleep enhancement is believed to occur via agonist effects at membrane-bound G protein-coupled melatonin type 1 (MT$_1$) receptors, which inhibit the activity of neurons in the suprachiasmatic nucleus of the hypothalamus, the main circadian pacemaker (Dubocovich *et al.* 2003). Melatonin also binds to G protein-coupled melatonin type 2 (MT$_2$) receptors, which are also located on suprachiasmatic nucleus neurons and induce shifts in the phase of the circadian cycle (Dubocovich *et al.* 2003).

Ramelteon is a highly specific MT$_1$ and MT$_2$ agonist (Krystal 2009). It is substantially more potent than melatonin in affecting these receptors. It has an FDA indication for the treatment of sleep-onset insomnia only.

Clinical therapeutic effects as indicated by available studies. A sizable set of studies that have used a variety of dosages, formulations, and timings of dosing have been carried out to assess the effects of melatonin on individuals with sleep difficulty (Buscemi *et al.* 2005; Ferracioli-Oda *et al.* 2013). These studies indicate that melatonin seems to be associated with a modest improvement in sleep latency in insomnia patients. Whether the degree of improvement associated with melatonin use is sufficient to be perceived as beneficial by many insomnia patients remains unclear (Morin *et al.* 2015). Furthermore, the optimal dosage of melatonin for the treatment of insomnia has yet to be established. The strongest empirical support for the use of melatonin in treating insomnia is for its effects in improving sleep difficulties co-occurring with autism or other neurodevelopmental disorders (Niederhofer *et al.* 2003; Wirojanan *et al.* 2009).

Ramelteon has been shown in several placebo-controlled trials to have therapeutic effects only on sleep-onset difficulties (Krystal 2009).

Safety profile. Melatonin has highly selective effects on melatonin receptors, and as a result it has an excellent safety profile (Wilson *et al.* 2010). However, as mentioned earlier, the effects on MT_2 and melatonin type 3 (MT_3) receptors can affect physiology, although by far the most important clinical effect mediated by MT_2 and MT_3 binding is MT_2-mediated shifts in circadian rhythm (Dubocovich *et al.* 2003). This is believed to be responsible for the observation that melatonin is associated with greater therapeutic effects in those with delayed sleep phase syndrome, in which the circadian sleep-wake cycle is shifted forward, than in insomnia patients (Buscemi *et al.* 2005; Ferracioli-Oda *et al.* 2013).

Like melatonin, ramelteon has an excellent safety profile as a result of having pharmacological effects that are limited to melatonin receptors (Krystal 2009). It does not have abuse potential and is safe in those with sleep apnea and chronic obstructive pulmonary disease (Kryger *et al.* 2007, 2009).

Optimal target patient population. The available data indicate that melatonin should be considered as a first-line therapy for patients with insomnia occurring with autism and other neurodevelopmental problems as well as for those with insomnia occurring in the setting of circadian rhythm disorders (Buscemi *et al.* 2005; Ferracioli-Oda *et al.* 2013; Niederhofer *et al.* 2003; Wirojanan *et al.* 2009). In addition, melatonin can be considered for use by those with insomnia affecting only sleep onset.

Because ramelteon has effects only on sleep-onset difficulties, its use should be limited to those with only sleep-onset difficulties. It is especially well suited for use by those with obstructive sleep apnea and chronic obstructive pulmonary disease who have sleep-onset problems. It should also be considered for treating sleep-onset problems occurring in the setting of substance abuse or in individuals prone to substance abuse, but no studies have established its utility for this purpose.

Agents That Improve Sleep by Blocking Wake-Promoting Systems

Selective Histamine 1 Receptor Antagonists

Selective H_1 receptor antagonists promote sleep by blocking the arousing effects of histamine through antagonism of the H_1 receptor (Krystal *et al.* 2013b). The only highly selective H_1 receptor antagonist available is doxepin 3-6 mg. Doxepin was originally developed for the treatment of depression and is FDA approved for the treatment of depression and anxiety in dosages of 75-300 mg/day. In this dosage range, doxepin has clinically significant antagonism of adrenergic, serotonergic, and cholinergic receptors and the serotonin and norepinephrine transporters in addition to H_1 receptor antagonism (Krystal *et al.* 2013b). However, because H_1 receptor antagonism is by far doxepin's most potent effect, at low enough dosages this agent can have clinically significant effects only at H_1 receptors. The available evidence suggests that in the 3-to 6-mg range, doxepin is a highly selective H_1 receptor antagonist (Krystal *et al.* 2013b).

Available data from placebo-controlled trials carried out with doxepin 3 mg and 6 mg doses provided the first information about the clinical effects of selective wake-promoting

system antagonism and, as discussed earlier, indicated that they differ from the clinical effects of $GABA_A$ allosteric modulators (Krystal *et al.* 2013b). In addition to dosage and pharmacokinetics, which essentially determine the clinical effects of those other agents, the clinical effects of doxepin are dependent on factors such as time of day and the state of the patient (e.g., activity, stress, novelty) (Krystal *et al.* 2010, 2011, 2013b). This dependence of clinical effects on factors other than dosage and pharmacokinetics exists for all selective wake-promoting system antagonists and therefore represents a new paradigm for understanding the clinical effects of insomnia medications. As discussed earlier, the dependence of clinical effects of selective antagonists on factors other than dosage and pharmacokinetics reflects the fact that 1) the activity in the targeted wake-promoting systems is dependent on factors such as time of day and the state of the patient, and this will affect the degree of clinical effect occurring with antagonism; and 2) each wake-promoting system functions in parallel with other wake-promoting systems that are not blocked by selective antagonism, and the activity in these systems is also affected by factors such as time of day and patient state (Krystal *et al.* 2013b). The reason this is not the case for $GABA_A$ allosteric modulators is that they broadly inhibit all of the wake-promoting systems, and the clinical effects of enhancing $GABA_A$ activity are relatively less dependent on time of day and patient state (Krystal *et al.* 2013b).

Selective H_1 receptor antagonists used for the treatment of insomnia. Many medications that have H_1 receptor antagonist effects are currently available and used to treat insomnia (Krystal *et al.* 2013b). However, the only highly selective H_1 receptor antagonist currently used in the treatment of insomnia is doxepin in 3-and 6-mg/day dosages. It is approved by the FDA for the treatment of insomnia with an indication only for treating problems staying asleep.

Clinical therapeutic effects as indicated by available studies. The clinical trials carried out with doxepin 3 mg and 6 mg indicate that this medication has consistent therapeutic effects on sleep maintenance, in particular in the last third of the night, without consistent therapeutic effects on sleep-onset problems (Krystal *et al.* 2010, 2011, 2013b). Notably, the largest effect size appears not at peak blood level (3-4 hours after dosing) but in the last hour of an 8-hour night. As discussed earlier, this could not occur with a $GABA_A$ allosteric modulator without prohibitive morning impairment. It is hypothesized that the reason the therapeutic effects are greatest at the end of the night is that the activity of histamine neurons is relatively high during this period, whereas the activity in the parallel wake-promoting systems is relatively low (Krystal *et al.* 2013b). However, after waking, the activity in the histamine system may increase further, and the activity in parallel wake-promoting systems increases, thereby sustaining normal waking function despite significant H_1 blockade (Krystal *et al.* 2013b).

Effects on systems other than sleep-wake systems. Given the relatively greater potency of doxepin for H_1 receptors over other receptors, it should be possible in theory to find a dosage for each individual that causes clinically significant H_1 receptor antagonist effects and no effects on any other pharmacological systems. The observed clinical effects indicate that the 3-and 6-mg/day dosages achieve this type of selectivity for many individuals (Krystal *et al.* 2010, 2011). However, for some individuals,

these dosages may have effects other than H_1 receptor antagonism. When this is the case, the special advantages of highly selective antagonism are lost, and individuals may experience morning sedation and other adverse effects, including anticholinergic (e.g., dry mouth, constipation, blurred vision) and antiadrenergic (e.g., orthostatic hypotension) symptoms.

Optimal target patient population. Because of the pharmacological selectivity of doxepin 3 mg and 6 mg, it can have an improved risk-benefit profile over other agents when used to treat the type of problem that it specifically addresses: sleep-maintenance problems, in particular problems staying asleep at the end of the night (Krystal *et al.* 2013b). For this reason, doxepin 3-6 mg should be the treatment of choice for those individuals with difficulties staying asleep, in particular toward the end of the night, who do not have problems falling asleep. The lack of abuse potential suggests that this medication might be particularly useful in abuse-prone individuals with sleep-maintenance problems. The fact that H_1 receptor antagonism is the key mechanism of anti-allergy effects also suggests that this medication should be among the treatments of choice for sleep difficulties occurring with significant allergy symptoms.

Selective Hypocretin/Orexin Receptor Antagonists.

Hypocretin and orexin are both names given to the peptides released by neurons located in the lateral hypothalamus that are among the most important factors maintaining wakefulness (Krystal *et al.* 2013a; Sakurai

2014). The wake-promoting effects of these peptides are mediated by their binding to two receptors referred to as OX_1 and OX_2 (Sakurai 2014). Selective hypocretin/orexin receptor antagonists enhance sleep by blocking OX_1 receptors, OX_2 receptors, or both. The tremendous specificity of this effect is illustrated by the fact that there are only 10,000-20,000 hypocretin/orexin-releasing neurons in the entire brain (Sakurai 2014). This specificity enables drugs that block OX_1 and OX_2 receptors to promote sleep while having limited effects on other brain functions. However, because hypocretin/orexin neurons modulate activity in many brain areas, these agents would be expected to have some effects on functions other than sleep. Nonetheless, the relative lack of effect on areas of the brain mediating cognitive and motor function suggests that these agents may lack many of the adverse effects that have been associated with benzodiazepines and nonbenzodiazepines.

Selective hypocretin/orexin receptor antagonists used for the treatment of insomnia. There are three hypocretin/orexin receptor antagonists currently available for clinical use--suvorexant, lemborexant, and daridorexant--all of which are dual orexin (OX_1 and OX_2) receptor antagonists (DORAs) (Dauvilliers *et al.* 2020; Herring *et al.* 2016; Karppa *et al.* 2020; Michelson *et al.* 2014; Yardley *et al.* 2021; Zammit *et al.* 2020). The FDA granted these agents approval for the treatment of insomnia, with indications for treating sleep-onset and sleep-maintenance difficulties for all of them.

Clinical therapeutic effects as indicated by available studies. The clinical effects of suvorexant, lemborexant, and daridorexant have been documented in large-scale placebo-controlled trials (Dauvilliers *et al.* 2020; Herring *et al.* 2016; Karppa *et al.* 2020; Michelson *et al.* 2014; Mignot *et al.* 2022; Yardley *et al.* 2021; Zammit *et al.* 2020). These studies indicate that all of these medications have therapeutic effects on sleep onset and sleep maintenance, consistent with their FDA indications. However, relatively limited data are available for the FDA-approved dosage of suvorexant 10-20 mg (Herring *et al.* 2016).

Effects on systems other than sleep-wake systems. DORAs have minimal effects on systems other than the hypocretin/orexin system. As a result, the primary adverse effects of these agents are relatively limited and due to decreased hypocretin/orexin-mediated function. The primary such effect is daytime sedation or fatigue (Dauvilliers *et al.* 2020; Herring *et al.* 2016; Karppa *et al.* 2020; Michelson *et al.* 2014; Mignot *et al.* 2022; Yardley *et al.* 2021; Zammit *et al.* 2020).

Optimal target patient population. DORAs are among the agents that could be considered for first-line use in patients with problems both falling and staying asleep. An additional target population is insomnia patients with mild to moderate chronic obstructive pulmonary disease or obstructive sleep apnea because of evidence that these drugs do not exacerbate these conditions (Boof *et al.* 2022; Cheng *et al.* 2020; Sun *et al.* 2015, 2016). The amygdala, lateral septum, periaqueductal gray, and parabrachial nucleus have important projections to hypocretin/orexin neurons, which are believed to mediate stress-or anxiety-associated increases in arousal; thus, DORAs should in theory be particularly useful for patients with sleep problems occurring in the setting of stress or anxiety (Krystal *et al.* 2013a; Scammell and Winrow 2011). DORAs would also be expected to be particularly helpful for those trying to sleep at a time of day that is not their circadian sleep period on the basis of evidence that hypocretin/orexin neurons are the prime mediators of maintenance of sustained wakefulness during the usual circadian wake period (Krystal *et al.* 2013a; Zeitzer *et al.* 2020). However, additional studies are needed to determine whether these theoretical optimal target patient populations are actually best treated with DORAs.

Selective Alpha-1 Adrenergic Receptor Antagonists

Medications that are selective a_1-adrenergic receptor antagonists have long been available by prescription for the treatment of hypertension and benign prostatic hypertrophy. These agents include prazosin, silodosin, doxazosin, tamsulosin, alfuzosin, and terazosin. They may have sleep-enhancing effects by blocking the wake-promoting effects of norepinephrine, one of the important wake-promoting systems (Krystal and Davidson 2007; Krystal *et al.* 2013b; Saper *et al.* 2005). These drugs do this by blocking a_1-adrenergic receptors, which are primarily excitatory postsynaptic receptors. These agents have long been of interest for modulating anxiety (Charney and Redmond 1983). A sizable literature indicates that agents that dampen central noradrenergic neuronal activity or blunt noradrenergic system-mediated activation, such as a_1-adrenergic receptor antagonists, have clinical anxiolytic effects. Within this context, selective a_1-adrenergic receptor antagonists have found application in the treatment of sleep difficulties.

Because of their selectivity for a_1 receptors, these agents, like DORAs and selective H_1 antagonists, have the potential to improve sleep difficulties in patients with anxiety-related difficulties without causing many of the adverse effects that have limited the use of benzodiazepines and nonbenzodiazepines. A series of studies documented the therapeutic effects of prazosin on sleep difficulties in patients with PTSD (Goddard *et al.* 2010; Raskind *et al.* 2003, 2007, 2013; Taylor *et al.* 2008). However, more recently,

the largest studies conducted to date cast uncertainty on this picture because no significant effects of prazosin versus placebo were found on PTSD-associated nightmares and sleep disturbance (Raskind *et al.* 2018).

Selective a_1-adrenergic receptor antagonists used for the treatment of insomnia. Although several selective a_1-adrenergic receptor antagonists are available, the only one that has been studied extensively and used to any significant extent for treating sleep problems is prazosin (Goddard *et al.* 2010; Krystal and Davidson 2007; Raskind *et al.* 2003, 2007, 2013, 2018; Taylor *et al.* 2008). However, no selective a_1-adrenergic receptor antagonists have an FDA indication for treating insomnia.

Clinical therapeutic effects as indicated by available studies. The available studies, with the notable exception of the largest one, suggest that prazosin may improve sleep-maintenance difficulties and nightmares in patients with PTSD (Goddard *et al.* 2010; Krystal and Davidson 2007; Raskind *et al.* 2003, 2007, 2013, 2018; Taylor *et al.* 2008). Studies of the effects of this agent on primary insomnia or insomnia occurring with conditions other than PTSD have not been carried out.

Effects on systems other than sleep-wake systems. Prazosin has minimal effects on systems other than the noradrenergic system. As a result, the primary adverse effects of this agent are relatively limited and consist of orthostatic hypotension and associated dizziness (Goddard *et al.* 2010; Raskind *et al.* 2003, 2007, 2013; Taylor *et al.* 2008). Dry mouth, sweating, nasal congestion, and sedation also have been reported to occur.

Optimal target patient population. Prazosin can be considered for patients with sleep difficulties occurring in the setting of PTSD. Although studies are lacking, the use of this agent in treating sleep problems in patients with other anxiety disorders is of great interest. It also should be noted that prazosin is the only medication shown to have significant therapeutic effects on nightmares in those with and without PTSD. As a result, when the physician is faced with the need to treat nightmares in a patient who does not have PTSD, a trial of prazosin could be considered.

Nonselective Wake-Promoting System Antagonists

Some agents that were originally developed for the treatment of allergies are generally referred to as *antihistamines* because they all have significant H_1 receptor antagonism. However, none of these agents are particularly potent or selective H_1 receptor antagonists, and all have clinically significant effects on pharmacological systems other than the histamine system (Krystal *et al.* 2013b). Notably, agents such as doxepin and mirtazapine are more potent and selective H_1 receptor antagonists than any of these antihistamines, but they were never referred to by this name because they were originally developed for the treatment of depression and not allergies. As a result, they are generally referred to as *antidepressants*. Thus, it is important to appreciate that the terms *antihistamine* and *antidepressant* are more a reflection of the original targeted disorder than an indicator of drug pharmacology. A more appropriate term for these agents would be *nonselective antihistamines* or, for those with relatively broad pharmacological effects, *nonselective wake-promoting system antagonists*.

Nonselective antihistamines used for the treatment of insomnia. The nonselective antihistamines primarily used for the treatment of insomnia include agents that are available in many over-the-counter sleep treatments: diphenhydramine and doxylamine (Krystal *et al.* 2013b). They all have significant muscarinic cholinergic receptor antagonism in addition to H_1 receptor antagonism, and some have other important pharmacological effects (Krystal *et al.* 2013b). There is reason to believe that these nonhistaminergic effects influence both clinical effects on sleep problems and the side-effect profiles of these agents (Krystal *et al.* 2013b). Nonselective antihistamines promote sleep primarily by blocking the arousing effects of both histamine and acetylcholine.

Clinical therapeutic effects as indicated by available studies. Remarkably little systematic research has been carried out on the sleep effects of nonselective antihistamines considering how frequently these agents are used to treat sleep difficulties. Only two placebo-controlled trials have been completed (Glass *et al.* 2008; Morin *et al.* 2005). One, a crossover study that included 20 older adults with primary insomnia, indicated that diphenhydramine 50 mg decreased the number of awakenings compared with placebo but had no other significant effects on sleep problems (Glass *et al.* 2008). The other study evaluated diphenhydramine 25 mg in 120 adults with relatively mild insomnia and found that this medication led to significant improvement in self-reported sleep efficiency (time asleep/time in bed) but not in polysomnographic sleep efficiency or self-reported or polysomnographic sleep-onset latency or total sleep time (Morin *et al.* 2005).

Effects on systems other than sleep-wake systems. The adverse effects of nonselective antihistamines include, in addition to daytime sedation, dry mouth, dizziness, constipation, and blurred vision (Glass *et al.* 2008; Krystal *et al.* 2013b; Morin *et al.* 2005). Cholinergic receptor antagonism also increases the risk for urinary retention, memory impairment, and delirium, in particular in older individuals.

Optimal target patient population. The limited available data do not make a strong case for the utility of nonselective antihistamines. However, to the extent that they have therapeutic effects, these agents appear to be limited to improvements in sleep maintenance and not sleep onset (Glass *et al.* 2008; Morin *et al.* 2005). Thus, use should be limited to those without sleep-onset difficulty who have problems with sleep maintenance. The H_1 and cholinergic receptor antagonism of the agents suggests that they would be best suited for use by individuals experiencing sleep problems related to allergies or those with nasal congestion.

Antidepressants

The group of agents initially developed for the treatment of depression are often referred to as *antidepressants*. They have broad pharmacological effects, being antagonists at several receptors, including at least one wake-promoting system, which leads these medications to have sleep-promoting effects (Krystal 2010). These medications are used off-label for the treatment of insomnia, often at dosages lower than the antidepressant dosage. With a few exceptions, the risk-benefit profile of these antidepressant medications for the treatment of insomnia has not been evaluated in placebo-controlled trials. This is a significant limitation to their use in an evidence-based approach to insomnia therapy. However, it can be assumed that their nonspecific pharmacology leads them to have therapeutic effects on conditions other than insomnia--some of which are common comorbid conditions, such as depression, anxiety, and pain--but at the same time associates these medications with a relatively high side-effect burden (Krystal *et al.* 2013b).

Antidepressants used for the treatment of insomnia. The antidepressants most commonly used to treat insomnia include amitriptyline, doxepin, trimipramine, trazodone, and mirtazapine (Krystal 2010). Amitriptyline, doxepin (25-50 mg), and trimipramine promote sleep primarily through antagonism of norepinephrine, histamine, and acetylcholine receptors, whereas trazodone promotes sleep primarily through antagonism of norepinephrine, histamine, and serotonin type 2 ($5\text{-}HT_2$) receptors. Mirtazapine promotes sleep primarily through antagonism of histamine and $5\text{-}HT_2$ receptors.

Clinical therapeutic effects as indicated by available studies. Among the antidepressants used to treat insomnia, double-blind, placebo-controlled studies of insomnia treatment have been carried out only with trimipramine, doxepin (25-50 mg), and trazodone (Krystal 2010). Trimipramine has been studied at dosages from 50 mg to 200 mg and has been found to improve self-reported sleep quality and sleep efficiency (total sleep time/time in bed) but not sleep-onset latency (Hohagen *et al.* 1994; Riemann *et al.* 2002). Studies carried out with doxepin 25-50 mg indicated that, unlike with doxepin 3-6 mg, therapeutic effects on sleep onset, sleep maintenance, and sleep quality were seen (Hajak *et al.* 1996, 2001; Rodenbeck *et al.* 2003). Trazodone has been found to have therapeutic effects on sleep when used as adjunctive treatment to antidepressant medications in depressed patients with insomnia (Kaynak *et al.* 2004; Nierenberg *et al.* 1994). Trazodone (50 mg) also was evaluated in a placebo-controlled trial in patients with primary insomnia, and although improvement was reported in some sleep indices in the first week of treatment, trazodone's effects did not separate from placebo in the second week of this 2-week study (Walsh *et al.* 1998). A pilot trial of trazodone as a treatment for insomnia in abstinent alcoholic individuals suggested therapeutic effects on sleep-maintenance problems (Le Bon *et al.* 2003).

Effects on systems other than sleep-wake systems. All of the antidepressants with sleep-enhancing effects have effects on pharmacological systems other than those related to enhancing sleep. Some of these effects can be assets to therapy because they involve therapeutic effects on conditions that often co-occur with sleep disturbance (Krystal 2010; Krystal *et al.* 2013b). However, some non-sleep-related effects may lead to adverse effects. The specific adverse effects seen depend on both the mechanism of action and the dosage. The higher the dosage, the greater the effects on more pharmacological systems, including those mediating side effects. Agents with significant muscarinic receptor antagonism are associated with a risk of dry mouth, constipation, blurred vision, urinary retention, dizziness, memory impairment, and delirium (Krystal 2010; Krystal *et al.* 2013b). Antidepressants with significant adrenergic receptor antagonism are associated with a risk of orthostatic hypotension and dizziness (see appendix table at the end of this chapter). Weight gain, although incompletely understood, appears to be particularly likely with agents with histamine, 5-HT$_2$, and acetylcholine receptor antagonism.

Optimal target patient population. Antidepressants with sleep-enhancing effects are best suited for use by patients with sleep problems occurring in conjunction with a condition that these agents effectively treat. These conditions vary depending on the

medication but may include depression, anxiety, or pain (Krystal 2010) (see appendix table at the end of this chapter). Two main approaches are used for treating insomnia comorbid with another such condition. One is to administer single-agent therapy with one of these antidepressants at a dosage at which there are established antidepressant, anxiolytic, or pain effects. The other is to combine a sleep-targeted drug with a treatment aimed at improving the associated condition. No data indicate which approach is preferred. However, an advantage of the two-treatment approach is that it allows a wider range of treatments for the associated conditions, including nonsedating interventions. For example, in a depressed patient with insomnia disorder, one could combine bupropion as an antidepressant with a sleep-targeted intervention; bupropion alone lacks sleep-enhancing effects and thus could not reasonably be used as a single-agent therapy (Krystal *et al.* 2007b). Antidepressants also can be considered for use in treating treatment-resistant insomnia because of their broad pharmacological effects.

Antipsychotics

Antipsychotics share similarities to antidepressants in being medications with broad pharmacological effects that were developed for an indication other than insomnia disorder but are used off label in treating insomnia at lower-than-usual dosages. These agents were developed for the treatment of psychosis, although some have more recently received FDA indications for bipolar mania and depression as well. Like antidepressants, antipsychotics are antagonists at several receptors, at least one of which includes receptors of a wake-promoting system, which is the basis for their sleep-promoting effects (Krystal 2010; Krystal *et al.* 2008b). Very limited data are available on the risk-benefit profile of these medications for the treatment of insomnia. In fact, even fewer placebo-controlled trials have been carried out with antipsychotics than with antidepressants, which is a significant limitation to including antipsychotics in an evidence-based approach to insomnia therapy. However, it can be assumed that their nonspecific pharmacology leads them to have therapeutic effects on conditions other than insomnia--some of which are common comorbid conditions, such as schizophrenia, mania, delirium, depression, anxiety, and pain--but at the same time associates these medications with a relatively high side-effect burden (Krystal 2010; Krystal *et al.* 2008b, 2013b).

Antipsychotics used for the treatment of insomnia. The antipsychotics most commonly used to treat insomnia include olanzapine and quetiapine (Krystal 2010; Krystal *et al.* 2008b). Both of these agents promote sleep primarily through antagonism of histamine, norepinephrine, acetylcholine, 5-HT_2, and dopamine receptors (Krystal 2010; Krystal *et al.* 2008a).

Clinical therapeutic effects as indicated by available studies. No large-scale systematic studies of the use of any of these agents in the treatment of insomnia have been performed. Several small studies were carried out in healthy control subjects and patients with schizophrenia and mood disorders and included polysomnographic endpoints that provided a preliminary indication that olanzapine improves both sleep-onset and sleep-maintenance problems (Krystal 2010). An open-label trial of quetiapine 25-75 mg in primary insomnia patients provided preliminary evidence that this agent improves sleep-onset latency and total sleep time (Krystal 2010). A double-blind, placebo-controlled, randomized trial of quetiapine 25 mg was carried out in 13 insomnia patients but did not find any statistically significantly greater effects of drug compared with placebo (Tassniyom *et al.* 2010).

Effects on systems other than sleep-wake systems. All of the antipsychotics with sleep-enhancing effects have effects on pharmacological systems other than those related to enhancing sleep. Some of these effects can be assets to therapy because they involve therapeutic effects on conditions that often co-occur with sleep disturbance, including schizophrenia, mania, depression, anxiety, and pain (Krystal 2010; Krystal *et al.* 2008b). However, some non-sleep-related effects may lead to adverse effects. Like with antidepressants, the specific adverse effects seen with antipsychotics depend on both the mechanism of action and the dosage. The higher the dosage, the greater the effects on more pharmacological systems, including those mediating side effects (see appendix table at the end of this chapter). Those agents with significant dopamine receptor antagonism are associated with a risk of parkinsonian side effects, acute dystonic reactions, and tardive dyskinesia (Krystal *et al.* 2008b). Those with muscarinic cholinergic receptor antagonism are associated with a risk of dry mouth, constipation, blurred vision, urinary retention, dizziness, memory impairment, and delirium (Krystal 2010; Krystal *et al.* 2013b). Those with significant adrenergic receptor antagonism are associated with a risk of orthostatic hypotension and dizziness. Weight gain, although incompletely understood, appears to be particularly likely with agents with histamine, 5-HT_2, and acetylcholine receptor antagonism.

Optimal target patient population. Antipsychotics with sleep-enhancing effects are best suited for use by patients with sleep problems occurring in conjunction with a condition that the agents effectively treat. These conditions vary depending on the medication but may include schizophrenia, mania, delirium, depression, anxiety, or pain (Krystal 2010; Krystal *et al.* 2008a) (see appendix table). Antipsychotics also can be considered for use by treatment-resistant insomnia patients because of their broad pharmacological effects, but the cost of this relatively broad pharmacological effect is a relatively unfavorable side-effect profile that must be taken into account when deciding whether to administer these agents.

Conclusion

An increasing number of medications is becoming available to help patients with insomnia. For many years, investigators believed that the mechanism of action of insomnia medications was without clinical implications. Clinical effects were assumed to be determined primarily by dosage and drug pharmacokinetic properties. It is now clear that this is not the case. The mechanism of action matters. Clinical effects reflect not only dosage and pharmacokinetics but also the specific properties of the pharmacological system(s) being modulated by a given drug and the nature and state of other parallel pharmacological systems that continue to function during the period of action of that drug. As a result, factors such as time of day, the behavior of the patient, and the patient's psychosocial context (e.g., stress, novelty, excitement) can play a role in determining the clinical effects of medications used to treat insomnia. This has become apparent only through experience with the relatively more recently available agents, including selective antagonists of a single wake-promoting system. In comparison with older, more broadly acting agents, these medications promise an improved risk-benefit ratio for specific subgroups of patients who have the particular type of sleep problem targeted by the given selective wake-promoting system antagonist. Taking advantage of this potential requires knowledge of the specific clinical effects of each agent and the type of sleep difficulty that they best treat. It is also important to appreciate the instances when it is best to use a nonselective, more broadly acting agent. Knowledge of the properties of each agent and the best target patient subpopulation can then serve as a basis for optimally matching patients to therapies in clinical practice.

APPENDIX

Properties of Agents Commonly Used to Treat Insomnia

345

346

Properties of agents commonly used to treat insomnia

Agent	Enhancement of	Blockade of	FDA indication	Usual dosage (mg)	Elimination half-life (hours)	Target sleep aspect[a]	Common adverse effect
Benzodiazepines							
Triazolam	GABA	--	Insomnia	0.125-0.8	2-5.5	Onset and maintenance	Motor and cognitive impairmen abuse potential, sedation
Temazepam	GABA	--	Insomnia	7.5-30	8-20	Onset and maintenance	Motor and cognitive impairmen abuse potential, sedation
Flurazepam	GABA	--	Insomnia	15-30	40-250	Onset and maintenance	Motor and cognitive impairmen abuse potential, sedation
Lorazepam	GABA	--	Anxiety, status epilepticus	0.125-1	12-15	None	Motor and cognitive impairmen abuse potential, sedation
Clonazepam	GABA	--	Panic disorder, seizures	0.25-2	35-40	None	Motor and cognitive impairmen

Note. 5-HT = serotonin; Ach = acetylcholine; COPD = chronic obstructive pulmonary disease; DA = dopamine; HA = histamine; N/A = not applicable; N

[a]At least one placebo-controlled trial reporting efficacy for either sleep-onset, sleep-maintenance, or end-of-night sleep difficulty.

Agent	Enhancement of	Blockade of	FDA indication	Usual dosage (mg)	Elimination half-life (hours)	Target sleep aspect[a]	Common adverse effect
							abuse potential, sedation
Alprazolam	GABA	--	Anxiety, panic disorder	1-3	12-14	None	Motor and cognitive impairmen abuse potential, sedation
Nonbenzodiazepines							
Zolpidem	GABA	--	Insomnia: sleep onset	5-10	2.0-5.5	Onset	Motor and cognitive impairmen abuse potential
Zolpidem extended release	GABA	--	Insomnia: sleep onset; sleep maintenance in first 6 hours of the night	6.25-12.5	2.0-5.5	Onset and maintenance	Motor and cognitive impairmen abuse potential, dizziness, somnolenc
Zolpidem sublingual	GABA	--	Insomnia: middle of the night	1.75-3.5	2.0-5.5	Middle-of-the-night insomnia	Motor and cognitive impairmen abuse potential
Zaleplon	GABA	--	Insomnia: middle of the night	10-20	0.9-1.1	Onset and middle-of-the-night insomnia	Motor and cognitive impairmen abuse potential
Eszopiclone	GABA	--	Insomnia: sleep onset and sleep maintenance	1-3	6-7	Onset and maintenance	Motor and cognitive impairmen abuse potential, sedation, metallic ta

---

Note. 5-HT = serotonin; Ach = acetylcholine; COPD = chronic obstructive pulmonary disease; DA = dopamine; HA = histamine; N/A = not applicable; N

[a] At least one placebo-controlled trial reporting efficacy for either sleep-onset, sleep-maintenance, or end-of-night sleep difficulty.

Agent	Enhancement of	Blockade of	FDA indication	Usual dosage (mg)	Elimination half-life (hours)	Target sleep aspect[a]	Common adverse effect
Selective melatonin receptor agonists							
Melatonin	Melatonin	--	N/A (available over the counter as herbal supplement)	0.3-10	0.6-1	Onset	Minimal
Ramelteon	Melatonin	--	Insomnia: sleep onset	8	0.8-2	Onset	Minimal
Selective histamine 1 receptor antagonist							
Doxepin	--	HA	Insomnia: sleep maintenance	3-6	10-50	Maintenance	Nausea, uppe respiratory infection, sedation

---

Note. 5-HT = serotonin; Ach = acetylcholine; COPD = chronic obstructive pulmonary disease; DA = dopamine; HA = histamine; N/A = not applicable; N

[a] At least one placebo-controlled trial reporting efficacy for either sleep-onset, sleep-maintenance, or end-of-night sleep difficulty.

Agent	Enhancement of	Blockade of	FDA indication	Usual dosage (mg)	Elimination half-life (hours)	Target sleep aspect[a]	Common adverse effect
Selective hypocretin/orexin receptor antagonists							
Suvorexant	--	Hypocretin/orexin	Insomnia: sleep onset and maintenance	10-20	9-13	Onset and maintenance	Cough, dry mouth, fatigue, abnormal dreams, headache, sedation
Lemborexant	--	Hypocretin/orexin	Insomnia: sleep onset and maintenance	5-10	17-19	Onset and maintenance	Abnormal dreams, headache, sedation
Daridorexant	--	Hypocretin/orexin	Insomnia: sleep onset and maintenance	25-50	8	Onset and maintenance	Fatigue, sedation, headache, nausea
Alpha-1 Adrenergic receptor antagonists							
Prazosin	--	NE	Hypertension	2-15	2-3	Maintenance in PTSD patients	Dizziness, nasal congestion dry mouth, sweating, orthostatic hypotensio
Nonspecific wake-promoting system antagonists							
Diphenhydramine	--	HA, Ach	Over-the-counter sleep and allergy medication	25-50	5-11	Maintenance	Sedation, dizziness, dry mouth, blurred vision, constipatio urinary retention
Nonspecific wake-promoting system antagonists *(continued)*							
Doxylamine	--	HA, Ach	Over-the-counter sleep and allergy medication	25-50	10-12	None	Sedation, dizziness, dry mouth, blurred vision, constipatio

---

Note. 5-HT = serotonin; Ach = acetylcholine; COPD = chronic obstructive pulmonary disease; DA = dopamine; HA = histamine; N/A = not applicable; N

[a]At least one placebo-controlled trial reporting efficacy for either sleep-onset, sleep-maintenance, or end-of-night sleep difficulty.

Agent	Enhancement of	Blockade of	FDA indication	Usual dosage (mg)	Elimination half-life (hours)	Target sleep aspect[a]	Common adverse effect
							urinary retention
Amitriptyline	--	NE, HA, Ach	Depression	10-100	10-100	None	Sedation, dizziness, weight gai orthostatic hypotensio dry mouth, blurred vision, constipatio urinary retention
Doxepin	--	NE, HA, Ach	Depression	25-75	10-50	Onset and maintenance	Sedation, dizziness, weight gai orthostatic hypotensio dry mouth, blurred vision, constipatio urinary retention
Trimipramine	--	NE, HA, Ach	Depression	25-100	15-40	Maintenance	Sedation, dizziness, weight gai orthostatic hypotensio dry mouth, blurred vision, constipatio urinary retention

Note. 5-HT = serotonin; Ach = acetylcholine; COPD = chronic obstructive pulmonary disease; DA = dopamine; HA = histamine; N/A = not applicable; N

[a] At least one placebo-controlled trial reporting efficacy for either sleep-onset, sleep-maintenance, or end-of-night sleep difficulty.

Agent	Enhancement of	Blockade of	FDA indication	Usual dosage (mg)	Elimination half-life (hours)	Target sleep aspect[a]	Common adverse effect
Nonspecific wake-promoting system antagonists *(continued)*							
Trazodone	--	5-HT_2, NE, HA	Depression	25-150	7-15	None	Sedation, dizziness, headache, dry mouth, blurred vision, orthostatic hypotensio priapism
Mirtazapine	--	5-HT_2, HA	Depression	7.5-30	20-40	None	Sedation, dry mouth, increased appetite, weight gai constipatio
Olanzapine	--	HA, NE, Ach, 5-HT_2, DA	Psychosis	2.5-20	20-54	None	Sedation, agitation, dizziness, constipatio orthostatic hypotensio akathisia, weight gai increased risk of cerebrovas lar events i dementia
Quetiapine	--	HA, NE, Ach, 5-HT_2, DA	Psychosis	25-200	7	None	Sedation, orthostatic hypotensio dry mouth, tachycardi weight gai

Note. 5-HT = serotonin; Ach = acetylcholine; COPD = chronic obstructive pulmonary disease; DA = dopamine; HA = histamine; N/A = not applicable; N

[a] At least one placebo-controlled trial reporting efficacy for either sleep-onset, sleep-maintenance, or end-of-night sleep difficulty.

CHAPTER 59

Treatment of Chronic Pain

R. Garrett Key, M.D.

Kurt Kroenke, M.D.

Pain is the most common symptom reported both by the general population and in the general medical setting (Kroenke 2003). Chronic pain is associated with decreased quality of life, opioid dependence, and poor mental health. According to the National Center for Health Statistics (Zelaya *et al.* 2020), in 2019 the prevalence of chronic pain in U.S. adults was 20.4%, and high-impact chronic pain, defined as pain that frequently limits life or work activities, was found in 7.4% of adults. The prevalence of pain increased with age and was highest (30.8%) in adults ages 65 years and older. Women, people from lower socioeconomic backgrounds, military veterans, and rural residents have been noted to have higher rates of chronic pain (Dahlhamer *et al.* 2018). In a report published in 2011, the Institute of Medicine estimated that chronic pain affected one in three Americans and resulted in medical costs and lost productivity amounting to $560-$635 billion annually.

Psychiatric Comorbidity

Pain is more prevalent in patients with psychiatric comorbidity (particularly mood disorders) than in those without, and it is a strong predictor of both the onset and persistence of depression (Ohayon and Schatzberg 2003).

Depression is likewise a powerful predictor of pain, particularly persistent pain (Bair *et al.* 2003; Gureje *et al.* 1998). Concurrent pain and depression have a much greater impact than either disorder alone on multiple domains of functional status as well as health care utilization. Comorbid depression worsens disability and decreases active coping in patients with pain (Arnow *et al.* 2006; Demyttenaere *et al.* 2008). Comorbidity decreases the likelihood of a favorable response of either condition to treatment and diminishes patient satisfaction with treatment (Bair *et al.* 2004; DeVeaugh-Geiss *et al.* 2010; Karp *et al.* 2005; Kroenke *et al.* 2008; Mavandadi *et al.* 2007; Thielke *et al.* 2007). Reliable methods

for assessing the presence and severity of pain in patients with depression, particularly those not responding to initial treatment, and strategies for effectively and efficiently integrating evidence-based depression care into the management of patients with chronic pain are sorely needed.

Although not as extensively studied, the comorbidity of pain with anxiety appears to be nearly as strong as its comorbidity with depression (Bair *et al.* 2008; Kroenke 2003; Kroenke and Price 1993; McWilliams *et al.* 2003). A global study conducted by the World Health Organization in 17 countries and involving more than 85,000 community-dwelling adults showed that pain is associated with mood and anxiety disorders, but not with alcohol use disorders (Gureje *et al.* 2008). In this study, the prevalence of specific mood and anxiety disorders was lowest among persons with no pain, intermediate among those with one pain site, and highest among those with multiple pain sites. Relative to persons not reporting pain, the age-sex adjusted odds ratios were 1.8 (95% CI = 1.7-2.0) for mood disorders and 1.9 (95% CI = 1.8-2.1) for anxiety disorders among persons with single-site pain, and 3.7 (95% CI = 3.3-4.1) for mood disorders and 3.6 (95% CI = 3.3-4.0) for anxiety disorders among those with multisite pain.

Definition and Classification of Pain

The International Association for the Study of Pain (IASP; 2012) defined pain as "an unpleasant sensory and emotional experience associated with, or resembling that associated with, actual or potential tissue damage." Although there are more complex approaches to classifying pain, a common approach broadly classifies pain as either nociceptive or neuropathic.

Nociceptive pain includes most cases of acute pain in which a strong, noxious stimulus impacts the skin or deep tissue. Acute pain resolves after the noxious stimulus has been removed, but inflammatory and other mechanisms may lead to the persistence of nociceptive pain for weeks, months, or years (i.e., chronic pain). Many pain conditions, including arthritis and other musculoskeletal disorders, migraine and tension headache, and chronic widespread pain conditions such as fibromyalgia, would be classified under the broad rubric of nociceptive pain.

Nociceptive pain can be further divided into somatic pain (triggered in the skin, muscles, joints, or fascia) and visceral pain (in the heart, lungs, gastrointestinal or genitourinary systems, or other deeper organs). Somatosensory fibers are precisely located in the spinal cord and brain, whereas afferent viscerosensory fibers overlap each other and converge at several levels within the nervous system. Visceral pain is diffuse and poorly localized, reflecting differences in innervation between somatic and visceral tissue.

Neuropathic pain arises from injury to the peripheral nervous system or CNS. Examples include postherpetic neuralgia, painful diabetic neuropathy, phantom limb pain, and sciatica. Neuropathic pain is often characterized as burning, paroxysmal, stabbing, buzzing, or electric shock-like. Some conditions, such as low back pain, may include both nociceptive components (arising from the muscles or contiguous tissues) and neuropathic components (radicular pain or sciatica).

Persons with chronic pain often have spontaneous ongoing pain. Allodynia is a condition in which pain due to a normally painless stimulus, like light touch, causes pain. Hyperalgesia

is a similar pain condition in which a stimulus that typically would produce mild pain instead causes much greater pain than would normally be expected. These phenomena may be related to central sensitization, which has been proposed as a common mechanism underlying unexplained pain syndromes such as fibromyalgia.

In this chapter we concentrate on the management of chronic pain due to nociceptive pain of the somatic variety and neuropathic pain conditions. Together these conditions account for the majority of chronic pain conditions seen in clinical practice. Of note, visceral pain is more commonly a harbinger of a serious underlying disorder, with specific treatments targeting the disease itself rather than mere analgesia.

Treatment of Pain

Overview

The focus of this chapter is twofold. First, we discuss major classes of medications as they relate to pain management. Because a number of drugs are effective across multiple types of pain disorders, it is useful to consider them in a cross-cutting as well as a disease-specific fashion. Second, nonpharmacological treatments are also reviewed. In the "Selected Pain Disorders" section we address several specific categories of disorders chosen because they account for the most common types of chronic pain, are conditions for which pain management is the principal focus, and have been studied in numerous clinical trials. Prevalence, pain management as a priority over disease modification, and evidence-based therapy are the three selection criteria for the discussion of specific disorders.

The prototypical diseases discussed are musculoskeletal disorders (principally fibromyalgia, low back pain, and osteoarthritis), headaches, and neuropathic pain. Acute pain (e.g., injuries, postoperative pain), cancer pain, and visceral pain are not addressed. Although pharmacotherapy receives the greatest attention in this chapter, we briefly review some nonpharmacological treatments used in the management of chronic pain.

Pharmacotherapy

Nonopioid Analgesics

The antiinflammatory properties of the extract of willow bark have been known for centuries. Salicylic acid was discovered as the extract's active ingredient in the nineteenth century and was subsequently acetylated to improve its gastrointestinal tolerability. Acetylsalicylic acid became the prototypical analgesic known as aspirin. Aspirin and other related compounds constitute a class of drugs known as nonsteroidal antiinflammatory drugs (NSAIDs). All NSAIDs have three desirable pharmacological effects: antiinflammatory, analgesic, and antipyretic effects. NSAIDs and acetaminophen are among the most commonly prescribed medications for pain.

Acetaminophen has analgesic and antipyretic effects similar to those of NSAIDs but notably lacks a specific antiinflammatory effect. Despite the widespread use of acetaminophen, its analgesic mechanism is poorly understood. Acetaminophen is a slightly weaker analgesic than NSAIDs (Towheed *et al.* 2006) but is a reasonable first-line option because of its more favorable safety profile and low cost. Acetaminophen is associated with asymptomatic elevations of aminotransferase levels at dosages of 4 g/day even in healthy adults, although the clinical significance of these findings is uncertain (Watkins *et al.* 2006). Thus, known liver disease is a reason either to use analgesics other than acetaminophen or to lower the maximum daily dose of acetaminophen to 2,000 mg or less.

NSAIDs block the enzymatic activity of cyclooxygenase (COX), which uses arachidonic acid to generate prostanoids. Prostanoids influence immune, cardiovascular, gastrointestinal, renovascular, pulmonary, CNS, and reproductive function. Although gastrointestinal adverse effects have traditionally been considered the most common and worrisome complication of use of nonsteroidal antiinflammatory drugs, cardiovascular risk has gained increasing attention (Antman *et al.* 2007).

There are two major COX isoenzymes: COX-1 is expressed constantly in most tissues, whereas COX-2 is induced by inflammation. NSAIDs vary in their chemical structure and relative ability to block the COX-1 versus COX-2 isoenzymes. Several prostaglandins are both hyperalgesic and gastroprotective. Thus, nonselective COX inhibition with NSAIDs like aspirin, ibuprofen, indomethacin, and naproxen, which inhibit both COX-1 and COX-2 enzymes, provides effective pain relief for inflammatory conditions but carries a risk for erosive gastritis and gastrointestinal bleeding. Selective COX-2 inhibitors (valdecoxib, rofecoxib, celecoxib) have less gastrointestinal toxicity because of the relative paucity of COX-2 expression in the gastrointestinal tract compared with inflammatory tissue. However, data from meta-analyses and registries have shown an increased risk of cardiovascular events and mortality from use of COX-2 inhibitors, particularly in patients with known cardiovascular disease who receive prolonged treatment. Rofecoxib (Vioxx) was withdrawn from the market in 2004, and all COX-2 inhibitors should be used cautiously, if at all, by patients with cardiovascular disease or risk factors for cardiovascular disease. All NSAIDs, including nonselective COX inhibitors and COX-2 agents, appear to be equally effective in the treatment of pain disorders (Chou *et al.* 2006). The NSAID that appears to be the safest in terms of cardiovascular risk is naproxen.

In July 2015, the FDA decided to strengthen its existing label warning that NSAIDs increase the chance of a heart attack or stroke. Although there is some risk even with short-term use or in patients without a history of cardiovascular disease or risk factors, both a longer duration of use and the presence of cardiovascular disease or risk factors substantially increase cardiovascular risk in patients receiving NSAIDs. However, the actual increased risk in a specific patient is still low. Given the prevalence of and disability associated with chronic pain and the limitations of other treatment options, NSAIDs are likely to remain a staple of pain management. Concerns about long-term use are focused on special populations, including those at greater risk for cardiovascular (e.g., known cardiovascular disease or more than two cardiovascular risk factors), gastrointestinal, or renal complications (Marks *et al.* 2012).

Opioid Analgesics

The analgesic effects of opium have been known for more than 5,000 years. However, their inherent abuse risk soon became evident. Ever since, society has attempted to find a balance between licit and illicit use, therapeutic and adverse effects, and medical needs and legal issues. Despite all the legal, administrative, and social interference associated with opioid use, no other class of drugs has remained in use for as long as opioids (Schug 2005).

Currently there are five known types of opioid receptors: mu (m), kappa (k), delta (d), nociceptin, and zeta (z). These receptors are responsible for the various physiological responses to opioid compounds. m Opioid receptors are related to analgesia, physiological dependence, euphoria, respiratory depression, miosis, constipation, and vasodilation. k Opioid receptor agonism causes analgesia, diuresis, and dysphoria. d Opioid receptors are related to analgesia and constipation. Nociceptin opioid receptors produce analgesia or hyperalgesia, depending on the concentration of the agonist present. z Opioid receptors are thought to be involved in cellular developmental processes unrelated to analgesia (Dhaliwal and Gupta 2023). Individuals vary in their sensitivity to the agonism of opioids at each receptor subtype, and also vary in cytochrome P450 (CYP) metabolism, receptor alleles, membrane transporters, and other factors. This heterogeneity gives rise to the variable clinical responses seen in terms of both analgesic benefit and side-effect burden (Smith 2008; Vieira *et al.* 2019).

Opioid treatment for chronic noncancer pain is typically reserved as a second-or third-line treatment because of ambiguity over the benefits of long-term opioid exposure and significant risks related to substance use disorders (SUDs), long-term effects (e.g., immunological, reproductive), opioid-induced hyperalgesia, and the increasingly complex regulatory environment.

The Controlled Substances Act of 1970 divided substances to be regulated into five schedules, as determined by the U.S. Drug Enforcement Administration. These schedules govern the legal distribution and use of most substances with a significant abuse liability. Schedule I drugs have the highest abuse potential. They are available for research only and have no approved medical uses. Schedule II-IV substances have decreasing abuse liabilities (II is the highest) and approved medical uses. Schedule II compounds have more stringent recordkeeping and storage requirements than Schedule III and Schedule IV substances. Schedule V substances have a recognized abuse liability but are generally not as highly regulated. Most opioids prescribed for pain are Schedule II substances, and each dispensation requires a new prescription. Notable exceptions are combination analgesics (e.g., those containing acetaminophen) that contain less than 90 mg of codeine per unit dose and buprenorphine, which are Schedule III substances. Tramadol, a centrally acting opioid analgesic with weak serotonin and norepinephrine reuptake inhibition, is a Schedule IV substance.

Opioids were initially reserved for short-term treatment of acute pain from conditions like surgery or trauma and palliation for cancer and other terminal diseases. In the 1990s advocacy for more aggressive treatment of chronic pain led to a sharp increase in the prescription of opioids (Nuckols and Chou 2014). An unintended consequence of this expansion of opioid availability was an increase in opioid use disorders. A total of 70,630 drug overdose deaths occurred in the United States in 2019, with around half of them involving synthetic opioids. The age-adjusted rate of synthetic opioid deaths rose from 1.0 per 100,000 to 11.4 per 100,000 between 2013 and 2019, an astounding 1,040% increase (Mattson *et al.* 2021). State and federal regulations are now being enacted to more closely regulate opioid prescription and dispensation to minimize the ongoing public health crisis.

Efficacy and adverse effects of opioids. Opioids continue to play a central role in the treatment of chronic pain, but the evidence supporting their use is not unequivocally supportive and serious risks are known. In two large systematic reviews (Busse *et al.* 2018; Chou *et al.* 2015) there were no studies that compared opioid-based treatment of chronic pain with nonopioid pain treatment strategies over 1 year or longer. There was clear evidence accumulating for the risk of serious harms with long-term opioid exposure, including overdose, abuse and misuse, fractures, myocardial infarction, motor vehicle accidents, and sexual dysfunction. Notably, no study in the analyses evaluated risks related to cognitive function; fall risk; infections; psychological changes; or the effectiveness of strategies to mitigate the risk of misuse, overdose, or the development of SUD (Chou *et al.* 2015).

When compared with placebo, opioids demonstrated small improvements in pain, physical function, and sleep quality that diminished over time and were notably reduced in studies longer than 3 months. A small but nonsignificant benefit in social function was seen, whereas no improvement in emotional function or role function was found compared with placebo (Busse *et al.* 2018). Opioids had side effects in excess of those seen with placebo related to vomiting, drowsiness, constipation, dizziness, nausea, dry mouth, and itching.

Opioids had benefits similar to NSAIDs, tricyclic antidepressants (TCAs), or nabilone (a cannabinoid) without evidence of superiority for pain relief or improvement in physical function. Opioids showed a small degree of superior pain relief compared with anticonvulsants. All of this evidence was found in studies of only 1-6 months' duration. Notably, there was not an association between opioid dosing and any of the outcomes. There likewise did not appear to be differential benefit for different pain conditions (e.g., neuropathic vs. nociceptive pain) from opioid treatment (Busse *et al.* 2018).

Evidence of the effect of opioid therapy for chronic pain on cognition is of limited quality and quantity but suggests that long-term exposure may negatively affect attention, language, orientation, psychomotor function, and several domains of memory (verbal/short term, episodic). It is notable that some studies show elements of improved cognition with opioid therapy, and it is speculated that this could be a benefit of improved pain control (Pask *et al.* 2020).

Endocrinological derangements from long-term opioid exposure are not uncommon. Proposed mechanisms for these changes include inhibition of gonadotropin-releasing hormone and stimulation of prolactin secretion. Hypogonadism, which is estimated to occur in more than 60% of male patients on long-term opioids, can manifest as sexual dysfunction and low libido. Male patients may report erectile problems, anorgasmia, or gynecomastia. Female patients' symptoms will more likely relate to menstrual irregularity. Hypercortisolism, which is estimated to occur in 15%-24% of individuals taking long-term opioids, may manifest as fatigue, malaise, anorexia, orthostasis, or abdominal discomfort. It is prudent to monitor all patients on long-term opioids for endocrine derangements related to testosterone, cortisol, and prolactin secretion (de Vries *et al.* 2020).

Tolerance and substance use disorders. The risks of prescription opioid addiction, abuse, and diversion among chronic pain patients are not well understood. In part this is because of inconsistent use of terminology and nuances among tolerance, physiological dependence, abuse, addiction, and SUD. Tolerance is the development of decreased responsiveness to a substance that may require dose escalation for continued equivalent benefit. Physiological dependence, which may occur in tandem

with tolerance, is the development of physiological need for continued administration of a substance to avoid withdrawal symptoms.

The stigmatizing terms *abuse* and *addiction* are now avoided in favor of *substance use disorder* defined in terms of mild, moderate, or severe degree. DSM-5 defines SUDs on the basis of 11 different criteria in the four major domains of impaired control over substance use, social problems as a consequence of substance use, risky use, and physiological tolerance or withdrawal (American Psychiatric Association 2013).

The evidence around SUDs and opioid treatment for chronic noncancer pain is of limited quality and quantity. Patients with SUD are typically excluded from studies of chronic pain intervention, which creates a vacuum of good data on this increasingly large population. Opioid management in patients with active or historical SUD is more complex, and close monitoring of analgesia, changes in activities of daily living, adverse reactions, and behaviors suggesting aberrant opioid use is recommended. The existing data suggest that the prevalence of SUDs in persons with chronic noncancer pain is relatively high, with estimates of the prevalence of active SUD ranging from 3% to 48%. Patients with a history of SUD are at increased risk for opioid misuse, but there are not sufficient data to reliably quantify the risk. Patients with SUD who adhere to treatment appear to receive pain relief benefits similar to those received by patients without SUD (Morasco *et al.* 2011). Another systematic review found that 11.5% of patients with chronic noncancer pain who were prescribed opioids developed aberrant medication use behaviors. Studies that specifically excluded patients with a history of SUD saw only 0.6% of participants develop aberrant medication behaviors (Fishbain *et al.* 2008). Notably, patients with other psychiatric comorbidity, particularly anxiety and depressive disorders, are at higher risk for the development of problematic opioid use when treated for chronic pain (van Rijswijk *et al.* 2019). All patients being treated for chronic pain with or without opioids should be screened periodically for psychiatric comorbidities.

General principles of opioid use. Opioids should be used judiciously and sparingly in the management of chronic pain, given the limitations of supporting evidence and the known risks we have outlined. Patients should understand that the goal of treatment is not the complete elimination of pain but a 25%-50% reduction in its intensity and improvement in mood and function. Opioid therapy should be initiated with less potent agents with escalation to higher doses or more potent agents as needed.

The use of heroically high doses of opioids is rarely helpful. The highest daily dose of opioids used in existing trials is 180 mg of morphine or its equivalent, and in typical clinical contexts, opioid reduction or rotation should be considered at this point or earlier. The initial dosage of a new opioid should be equivalent to 50% or less of the dosage of the original opioid because of incomplete cross-tolerance. Approximate equianalgesic doses of oral and transdermal opioids are summarized in Table 59-1. It should be noted that these values are based on limited data and that opioid effects can vary significantly among individuals in terms of analgesia and side effects.

TABLE 59-1. Oral and transdermal analgesic equivalence of commonly used opioids

Drug	Dose (mg)	Duration (hours)[a]

[a] The duration of analgesia is dose dependent; the higher the dose, usually the longer the duration.

[b] These high doses of codeine and meperidine are not recommended clinically.

[c] Equianalgesic data are more variable for hydrocodone than for most other opioids.

[d] For opioid-tolerant patients converted to methadone, starting doses should be 10%-25% of the equianalgesic dose. Also, the half-life of methadone can vary widely, from 12 to 190 hours.

[e] 1 mg/hour transdermally is approximately equal to morphine 2 mg/24 hours orally.

Drug	Dose (mg)	Duration (hours)[a]
Morphine	30	2-4
Codeine	200[b]	3-4
Hydrocodone	30-40[c]	4-6
Oxycodone	20	4-4
Hydromorphone	7.5	4-4
Meperidine	300[b]	4-4
Methadone	20[d]	4-8
Fentanyl (transdermal)	12.5 mg/hour[e]	48-72

[a] The duration of analgesia is dose dependent; the higher the dose, usually the longer the duration.

[b] These high doses of codeine and meperidine are not recommended clinically.

[c] Equianalgesic data are more variable for hydrocodone than for most other opioids.

[d] For opioid-tolerant patients converted to methadone, starting doses should be 10%-25% of the equianalgesic dose. Also, the half-life of methadone can vary widely, from 12 to 190 hours.

[e] 1 mg/hour transdermally is approximately equal to morphine 2 mg/24 hours orally.

Opioid rotation is the practice of changing a drug or route of administration to achieve better outcomes in terms of either analgesia, side effects, or both. Potential indications for opioid rotation may include intolerable side effects; inadequate analgesia despite dose escalation; problematic drug interactions; the need for a new route of administration; or a change in clinical status that may affect pharmacokinetics, such as renal or hepatic impairment (Fine and Portenoy 2009).

The equianalgesic table was developed in 1966 and has been modified very little since that time (Houde *et al.* 1966). Advancements in our understanding of the complexity of opioid response, including incomplete cross-tolerance and variability among individuals, have given rise to a recommended two-step process to safely cross over from one opioid to another. This method reduces risks of accidental overdose while attempting to maintain adequate analgesia. First, calculate the equianalgesic dose of the new opioid using the equianalgesic table and initiate the new opioid at 25%-50% of the calculated equianalgesic dose. Second, rapidly reassess pain and adjust the dose up or down by 15%-30% depending on the clinical response to the initial dose. Two notable exceptions are methadone, which requires an initial dose reduction of 75%-90%, and transdermal fentanyl, which should be dosed according to the tables found in the package (Fine and Portenoy 2009).

When trials of several opioids are ineffective in treating chronic pain, it is appropriate to consider tapering and discontinuation of opioid therapy. Tapering schedules will vary among individuals, and care should be taken to avoid precipitating withdrawal or pain crisis with overly aggressive reduction timelines. For patients on high doses, outpatient discontinuation may be a process that can take months. A gentle schedule of 5%-20% dose reduction every 4 weeks may be optimal for patients with a longer duration of opioid treatment. Some patients with shorter exposure or lower doses may tolerate a 5%-20% reduction per week. In cases of SUD, referral to an SUD specialist may be optimal so that a more comprehensive, psychosocially informed plan can be made to manage the patient's pain and SUD together (Rosenberg *et al.* 2018). A review of 13 guidelines addressing opioid prescribing in adults with chronic pain found that most guidelines recommend that clinicians 1) avoid daily doses greater than 90-200 mg of morphine equivalents (ideally less than 100 mg); 2) have additional knowledge to prescribe methadone (as well as buprenorphine); 3) recognize

the risks of fentanyl patches, titrate cautiously, and reduce doses by at least 25%-50% when switching opioids; and 4) use opioid risk assessment tools, written treatment agreements, and urine drug testing to mitigate risks (Nuckols and Chou 2014). However, most recommendations are supported by observational data or expert consensus rather than findings from clinical trials. Principles for the use of opioids in the treatment of chronic pain are summarized in Table 59-2.

TABLE 59-2. Opioid management strategy for the treatment of chronic pain

1. Maximize nonopioid analgesic strategies first.
2. Inform patient of risks, including substance use disorder, before initiating opioid therapy.
3. Although the evidence is not strong, four strategies are variably encouraged by some expert pain groups or are mandated by prescribing regulations in some states:
    a. Opioid risk tools: Stratify risk with screening measures such as the Opioid Risk Tool and the Screener and Opioid Assessment for Patients with Pain.
    b. Opioid agreements (contracts): Consider the use of opioid agreements (contracts) for patients initiating or increasing opioids. Key points to stipulate include the frequency of obtaining medications, timely refills but no early replacement of lost or stolen prescriptions, safe storage, no sharing, single-source prescribing, monitoring through urine screens, and adherence to monitoring visits. The benefit of these agreements and their medicolegal validity is not well established.
    c. Urine drug screening: Conduct initial and periodic urine drug screening for opioids as well as illicit drugs.
    d. Prescription drug monitoring program: Use the state prescription drug monitoring program to monitor all sources of controlled substances.
4. Immediate-release opioids are recommended for initial therapy and breakthrough pain, although sustained-released opioids may have an important role in long-term therapy.
5. A short-acting opioid dose is typically 10%-20% of the total daily dose (e.g., if 24-hour scheduled morphine totals 50 mg, give 5-10 mg short-acting morphine for breakthrough pain).

Source. Adapted from Chou *et al.* 2014; Dowell *et al.* 2016; Nuckols and Chou 2014; Reuben *et al.* 2015.

6. Schedule follow-up visits at 2-to 3-month intervals, performing periodic urine testing to confirm adherence.
7. Monitor pain severity and pain-related functional impairment at follow-up visits to guide analgesic dose adjustments.
8. Avoid escalating the opioid dose without first assessing pain severity and interference.
9. View opioid initiation as an empirical trial. Consider discontinuing opioids if they are not beneficial.
10. Consider opioid rotation if inadequate response to one opioid occurs. Reduce the morphine-equivalent dose (MED) of the new opioid by 3%-50% to accommodate for unknown cross-tolerance and then titrate to goal.
11. If the patient is a high-risk candidate for opioids, consider referral to a pain specialist.
12. Minimize the use of sedative-hypnotics, benzodiazepines, and other controlled substances.
13. Consider referral to a pain specialty program if the MED exceeds 80-120 mg/day.

Source. Adapted from Chou *et al.* 2014; Dowell *et al.* 2016; Nuckols and Chou 2014; Reuben *et al.* 2015.

Long-acting opioids. A systematic review (Carson *et al.* 2011) compared the effectiveness and harms of long-acting opioids and also compared long-acting opioids with short-acting opioids in adults with chronic noncancer pain. The evidence was insufficient

to determine whether there are differences among long-acting opioids in effectiveness or harms, and no difference was found in pain relief or functional outcomes among various long-acting opioids. Evidence was insufficient to determine whether long-acting opioids as a class are more effective or are associated with fewer harms than short-acting opioids.

Methadone.

Methadone is a long-acting full agonist analgesic that is effective for pain control and also has been widely used as a maintenance drug in the treatment of opioid use disorder. The stigma from its reputation as a drug for addicts has been a factor limiting its use as an analgesic in clinical practice. It is commonly used in the treatment of intractable pain in end-of-life care and other palliative care settings. Concerns regarding the use of methadone to treat pain relate to its long and unpredictable half-life, which carries the risk of a delayed overdose in the days immediately following dose escalation. Large variations in equianalgesic doses of methadone relative to other opioids have been seen among individuals. This confounds the use of simple equianalgesic tables to calculate the required dose of methadone during rotation from other opioids. Despite the long half-life of methadone and its metabolites, dosing is required three to four times daily for optimal analgesia.

Although methadone has increasingly been used for the treatment of chronic noncancer pain, published data are rather modest. The current evidence base is inadequate and does not support methadone as a first-line treatment for chronic pain (Sandoval *et al.* 2005).

Regarding safety, a review of 168 studies found insufficient evidence to answer most safety questions, including risk factors associated with methadone overdose deaths and adverse events; the comparative mortality of methadone versus other opioids; the harms associated with methadone use during pregnancy; and the effects of risk mitigation strategies such as electrocardiogram monitoring, strategies for managing patients with prolonged QTc intervals on screening, urine drug testing, alternative dosing regimens for initiation and titration of therapy, and timing of follow-up (Weimer and Chou 2014).

Buprenorphine. Buprenorphine was introduced into the United States in 1985 as an opioid analgesic and like other opioids was found to have the potential to be abused intravenously. The opioid receptor antagonist naloxone was added to reduce the abuse potential, and the combination of buprenorphine and naloxone (Suboxone) was approved by the FDA in 2002 as a Schedule III drug for office-based SUD treatment. Compared with other opioids, buprenorphine has a somewhat lower potential for SUD because of partial agonism at opioid receptors rather than full agonism. The partial agonism produces less respiratory depression and other side effects than full agonism. The low dose of naloxone contained in the combination of buprenorphine and naloxone can reverse opioid effects if an attempt is made to use the combination preparation intravenously. When taken orally, as intended, the naloxone is not significantly bioavailable and does not interfere with the opioid activity of the buprenorphine.

Buprenorphine/naloxone is a sublingual combination tablet composed of buprenorphine and naloxone in a fixed 4:1 ratio. Although FDA approved only for SUD treatment, the combination can be effectively used off-label as a treatment for pain. This is particularly the case for patients currently or previously on opioids who have developed tolerance or, alternatively, SUD problems. For many years, all buprenorphine preparations required special credentialing, but in early 2021, federal regulations were updated to allow all prescribers to treat up to 30 patients without undergoing additional training and certification.

Buprenorphine preparations are typically prescribed once daily for medication-assisted treatment of opioid use disorder and suppression of opioid craving. Analgesic uses require dosing three to four times daily to achieve optimal pain control. Buprenorphine can be particularly useful for the management of opioid analgesia in patients with SUDs because of its utility in reducing opioid craving, availability in diversion-resistant preparations (i.e., the combination of buprenorphine and naloxone), and safety in overdose.

The initiation of buprenorphine in patients already taking opioids must be done with care as the partial agonist buprenorphine will displace other opioids from opioid receptors and induce acute withdrawal symptoms. To avoid the precipitation of acute withdrawal and possibly pain crisis, patients should stop their current opioids and take an initial dose of buprenorphine only after beginning to show mild signs of opioid withdrawal.

Antidepressants

Tricyclic antidepressants.

TCAs have been used for many years in the treatment of a wide variety of pain conditions. Lower dosages of TCAs have been used in clinical trials of pain management (e.g., 25-100 mg/day of amitriptyline or equivalent) compared with the dosages used for treating depression. The mechanism of action of TCAs is similar to that of the newer class of serotonin-norepinephrine reuptake inhibitors (SNRIs), and their benefit in pain conditions is thought to occur through similar pathways.

Advantages of TCAs include good evidence from multiple clinical trials, decades of clinical experience with TCAs in pain management, and the low cost of these generic agents. Disadvantages of TCAs include side effects like cardiovascular concerns (hypertension, postural hypotension, arrhythmias), an increased risk of falls in elderly patients, and potential lethality in overdose.

Selective serotonin reuptake inhibitors. Although selective serotonin reuptake inhibitors (SSRIs) may be useful in the co-management of anxiety and depression in the context of pain, their efficacy and adjuvant analgesics have not been clearly established. Existing data are heterogeneous and of low quality, which precludes clear recommendation of their use in the treatment of chronic pain (Patetsos and Horjales-Araujo 2016).

Serotonin-norepinephrine reuptake inhibitors. ***Duloxetine.*** A review of 30 trials involving individuals with diabetic neuropathy (12 trials), fibromyalgia (9 trials), low back pain (6 trials), and osteoarthritis (3 trials) found that the SNRI antidepressant duloxetine at a dosage of 60 mg once daily was effective in reducing pain in all four conditions (Pergolizzi *et al.* 2013). Duloxetine showed a rapid onset of action, with separation from placebo beginning at week 1. In a number of trials, both patients with depression and those without depression were enrolled, although path analysis estimated that more than two-thirds of the analgesic effect in duloxetine-treated patients was attributable to a direct analgesic effect, with less than one-third possibly explained by an antidepressant effect (Brannan *et al.* 2005; Brecht *et al.* 2007; Marangell *et al.* 2011; Perahia *et al.* 2006).

Milnacipran. Approved some years ago in Europe for the treatment of depression, milnacipran is comparable to SSRIs as an antidepressant (Papakostas and Fava 2007). Although milnacipran is FDA approved only for the treatment of fibromyalgia, levomilnacipran (an enantiomer of milnacipran branded Fetzima) is FDA approved for the treatment of depression. Substantial data confirm the effectiveness of milnacipran 100 mg/day or 200 mg/day for fibromyalgia-related pain, although there are not adequate data to demonstrate its efficacy for neuropathic pain (Derry *et al.* 2012). A meta-analysis of 5 milnacipran trials (4,129 patients), 4 duloxetine trials (1,411 patients), and 10 amitriptyline trials (612 patients) showed all three drugs to be superior to placebo, with small differential effects of the drugs on several fibromyalgia symptoms but overall similar acceptability and effectiveness (Hauser *et al.* 2011). However, the methodological quality of the amitriptyline trials was poor compared with that of the trials of the other two drugs.

Venlafaxine. There is only modest evidence for the efficacy of venlafaxine in treating fibromyalgia--four open-label cohort studies and one randomized trial (VanderWeide *et al.* 2015). Evidence of limited quality exists supporting its efficacy in the broad category of neuropathic pain (Aiyer *et al.* 2016). Although used clinically in treating many pain conditions, venlafaxine is not FDA approved for any pain disorder, and high-quality evidence supporting its broad use remains to be found.

Other antidepressants. Mirtazapine was studied in a 6-week open-label trial of 594 patients with a primary diagnosis of at least one chronic pain syndrome ([?] 3 months) and a clinical diagnosis of depression (Freynhagen *et al.* 2006). The mean daily dose was 35 +- 10 mg at study endpoint, and a statistically significant reduction in pain ($P < 0.0001$) was found. Pain improvement was not related to age or type of pain syndrome.

Anticonvulsants

Anticonvulsant drugs have been used in the management of pain since the 1960s. The clinical impression is that they are useful for treating chronic neuropathic pain, especially when the pain is lancinating or burning. Three of the most extensively studied anticonvulsants are gabapentin, pregabalin, and carbamazepine. Gabapentin and pregabalin have the strongest evidence for the treatment of pain. These two gabapentinoids act as neuromodulators by selectively binding to the a_2d-subunit-subunit protein of calcium channels in various regions of the brain and the superficial dorsal horn of the spinal cord. This results in inhibition of the release of excitatory neurotransmitters that are important in the production of pain. Gabapentin and pregabalin are analogs of GABA, but they have no activity at GABA receptors and do not alter GABA uptake or degradation.

Gabapentin. Gabapentin has been widely used to treat neuropathic pain of all types. A systematic review updated in 2015 concluded that gabapentin in dosages of 1,800 mg/day to 3,600 mg/day, typically divided into three daily doses, can provide good relief from pain for people with postherpetic neuralgia (number needed to treat [NNT] = 6.7) and diabetic peripheral neuropathy (NNT = 6.6). Data are very limited for other pain states, which precludes an evidence-based recommendation for broad use of gabapentin to treat all neuropathic pain conditions (Wiffen *et al.* 2017).

Pregabalin. Pregabalin is a novel compound that has analgesic, anticonvulsant, and anxiolytic effects (Shneker and McAuley 2005). In 45 studies involving 11,906 participants, pregabalin at dosages of 300-600 mg/day was effective in improving pain in individuals with postherpetic neuralgia, painful diabetic neuropathy, and mixed or unclassified posttraumatic neuropathic pain. It was not found to improve HIV-related neuropathy (Derry *et al.* 2019). In fibromyalgia specifically, pregabalin at 300-600 mg/day, typically divided into two daily doses, significantly reduced pain for about 1 out of 10 patients over 12-26 weeks with concomitant improvement in quality of life and function (Derry *et al.* 2016). Whereas both pregabalin and gabapentin are FDA approved for neuropathic pain, only pregabalin is approved for fibromyalgia. Pregabalin, gabapentin, and duloxetine have similar efficacy for diabetic neuropathic pain (Quilici *et al.* 2009). The U.S. Drug Enforcement Administration has placed pregabalin in Schedule V of the Controlled Substances Act (indicating a low potential for abuse), possibly because of withdrawal symptoms that were found during clinical trials.

Carbamazepine. A systematic review of 11 trials included 480 participants with trigeminal neuralgia, diabetic neuropathy, and poststroke pain. Overall the quality and quantity of the evidence was low and the duration of the trials was short, at 4 weeks or less. The authors concluded that although carbamazepine is probably effective in some people with chronic neuropathic pain, the current data do not clearly indicate which conditions are most likely to benefit and the risk of adverse events is significant (Wiffen *et al.* 2014). Carbamazepine carries FDA black box warnings for serious dermatological reactions (toxic epidermal necrolysis and Stevens-Johnson syndrome) and aplastic anemia/agranulocytosis.

Other Pharmacological Agents

Tramadol. Tramadol is unique in that it has both opioid and nonopioid effects. It exerts an analgesic effect through m opioid receptor agonism (opioid effect) and weak inhibition of serotonin and norepinephrine reuptake (nonopioid effect). Tramadol is available in both short-and long-acting formulations. The starting dosage for the short-acting formulation is 50 mg once or twice daily, with gradual titration to a maximum of 400 mg/day. The risk of respiratory depression and, presumably, SUD is lower than with other opiates, but tramadol still should be used with caution. Dose reduction is recommended in older adult patients (> 65 years) and in those with renal impairment (creatinine clearance < 30 mL/minute) or cirrhosis of the liver. Multiple trials have demonstrated the efficacy of tramadol in treating pain disorders, including osteoarthritis, fibromyalgia, and neuropathic pain.

A systematic review of the evidence for the use of tramadol in neuropathic pain conditions included six randomized controlled trials (RCTs) involving 438 patients (Duehmke *et al.* 2017). The authors found modest evidence of very low quality that was additionally compromised by risk of bias and concluded that there is inadequate evidence to recommend the use of tramadol in the treatment of neuropathic pain.

A systematic review of tramadol, both alone and in combination with acetaminophen, found that it had little to no important benefit in improvement of mean pain or function in patients with osteoarthritis. High-quality evidence for tramadol's benefit in fibromyalgia is also lacking (Thorpe *et al.* 2018).

Skeletal muscle relaxants. Most skeletal muscle relaxants are approved by the FDA for treating either spasticity (baclofen, dantrolene, and tizanidine) or musculoskeletal pain (carisoprodol, chlorzoxazone, cyclobenzaprine, metaxalone, methocarbamol, and orphenadrine) (Chou *et al.* 2004). There is insufficient evidence to prove that skeletal muscle relaxants differ in their efficacy, adverse events, or safety. Most trials have focused on acute rather than chronic pain. Cyclobenzaprine is the best-studied muscle relaxant in musculoskeletal disorders overall. In 14 fair-quality trials, it was consistently proven superior to placebo for relieving pain, reducing muscle spasms, and improving functional status (Chou *et al.* 2004). Moreover, 5-mg doses of cyclobenzaprine are just as effective as 10-mg doses (each given three times daily) but cause fewer side effects. Also, 20-mg doses (three times daily) are not more effective than 10-mg doses, and they cause more side effects.

Topical analgesics. A potential advantage of topical agents is avoidance of the systemic side effects often associated with oral medications. Disadvantages are that only localized areas of pain can be effectively treated and that irritating skin reactions occur in a minority of patients. A Cochrane Review summary covering 13 smaller reviews totaling 206 studies and about 30,700 patients found limited efficacy for topical diclofenac and ketoprofen for osteoarthritis and also small benefit for postherpetic neuralgia from high-concentration topical capsaicin. The quality of evidence for other drug preparations and pain conditions was insufficient to support recommendations (Derry *et al.* 2017).

Cannabinoids. The social stigma associated with cannabinoids coupled with political and legal issues related to medical cannabis use have been barriers to research. Increases in the availability of both medical and recreational cannabis products and a more open regulatory environment have renewed interest in the study of these compounds for many conditions, including chronic pain. The presence of specific high-affinity cannabinoid type 1 receptor binding sites has been demonstrated in the CNS and in certain peripheral tissues, whereas cannabinoid type 2 receptors are expressed in high quantities in immune tissues and cells. Two main endogenous cannabinoids have been described, and their role in modulating pain has been increasingly recognized.

There are two FDA-approved cannabinoids (dronabinol and nabilone) for chemotherapy-associated nausea and vomiting and appetite stimulation in wasting illnesses. A review of cannabinoids for chronic pain included 13 different studies evaluating nabiximols, smoked tetrahydrocannabinol (THC), nabilone, THC oromucosal spray, dronabinol, oral THC, and ajuvenic acid capsules. The authors suggested that moderate-quality evidence existed that smoked THC and nabiximols may offer benefit to chronic pain conditions as a whole (Whiting *et al.* 2015). Despite advancements in cannabinoid science, many heterogeneous cannabinoid preparations (both legal and illicit) exist, which makes consistent dosing, potential efficacy, and adverse events rather unpredictable.

Ketamine. Ketamine, an analgesic that is thought to exert its effects via antagonism of *N*-methyl-D-aspartate receptors, also can be used for anesthesia. It has been studied in the treatment of chronic pain, but the quality of evidence remains modest, as described in reviews (Michelet *et al.* 2018; Orhurhu *et al.* 2019). In addition to the lack of high-quality evidence, it has largely been studied in intravenous preparations. Reliable information about the efficacy of oral ketamine in outpatient treatment of chronic pain is lacking. Ketamine may have a place in the standard treatment of chronic pain in the future.

Nonpharmacological Treatments

Psychotherapy and Behavioral Interventions

Nonpharmacological treatments are not discussed in detail but need to be mentioned because of their important role in the management of chronic pain. Medications are typically targeted to symptoms, but dysfunctional beliefs, attitudes, coping styles, and behaviors frequently develop in patients with chronic pain and contribute to its perpetuation and their disability. Pain can lead to depression, anxiety, disability, or loss of social contact. People can develop the view that life has been irreversibly ruined by pain or see their pain as a catastrophe that cannot be overcome The goals of psychological treatment for pain can be broadly placed into four categories: pain, mood, catastrophizing, and disability secondary to pain. Just as in other chronic medical disorders, pharmacotherapy is necessary but not sufficient for optimizing outcomes. A review (Williams *et al.* 2020) including 75 studies of psychological therapies for chronic pain (excluding headache) and 9,401 participants found the largest evidence base favoring the use of cognitive-behavioral therapy over active control or treatment as usual, with the quality of evidence in the moderate to low range. A variety of other behavioral therapies, such as mindfulness meditation variants, biofeedback, hypnosis, music, and art therapy, were included, and reliable benefit was not clearly demonstrated. The authors noted that the quality of evidence in these trials was very low.

Acceptance and commitment therapy was reviewed, and some studies suggested greater benefit for pain in comparison with treatment as usual and reduced disability compared with an active control condition. The authors were careful to "encourage caution when interpreting" this low-quality evidence (Williams *et al.* 2020).

In a separate article (Eccleston and Crombez 2017), an argument was put forward supporting the possibility of benefit existing but being undetectable because of the proliferation of small, poorly designed studies that flood the dataset with noise. Psychologically based therapies have a place in the management of chronic pain and, after one considers possible harms, they should be part of a comprehensive pain management plan. Future studies should focus on producing higher-quality evidence that can better guide future practice.

Exercise

A review of physical activity and exercise that included 21 systematic reviews covering 381 studies and 37,143 participants (Geneen *et al.* 2017) found a dearth of high-quality evidence and rated the quality of evidence overall as low. Nevertheless, exercise is supported as an intervention with few adverse events that may benefit pain severity, physical function, and overall quality of life.

Combination Therapy

The treatment of chronic pain often includes the stepwise addition of medications to a patient's regimen and deletion if a therapy shows no benefit. In addition to medications given to produce analgesia, pain management may include medications to treat the side effects of the analgesics, such as laxatives or stool softeners for patients receiving opioids, gastroprotective medications for those receiving NSAIDs, and psychostimulants to combat excessive somnolence.

Very few studies have tested combinations of treatments to determine their additive value compared with monotherapy. Only limited data suggest that the combination of acetaminophen and NSAIDs has additive pain-relieving effects (Schug 2005). The largest trial (892 community-derived subjects) found greater pain relief with the combination of acetaminophen and ibuprofen than with either drug alone (Doherty *et al.* 2011). More data show a beneficial effect of combining acetaminophen with opioids, including codeine, tramadol, and morphine. Indeed, one of the more common fixed combinations in a single pill has been the coupling of an opioid, such as codeine, tramadol, oxycodone, or hydrocodone, with a nonopioid analgesic such as acetaminophen or aspirin. Caution must be taken to avoid excessive amounts of acetaminophen beyond 4 g/day while escalating dosing when more analgesia is required. Head-to-head clinical trials comparing different analgesics for chronic pain, separately or in combination, are rare, and there is little high-quality evidence available.

When optimal pain relief has not been achieved it is necessary to decide whether to switch to a new treatment or to add to what is currently being provided. Given the paucity of combination drug trials, this decision is guided by practical considerations. Switching to another monotherapy is often less costly than combining two or more treatments and often is done when a patient has had only a minimal response to and/or poor tolerance of the initial treatment. However, adding a second treatment may be favored when there has been at least a partial response to the first therapy or when the second treatment has a different mechanism of action that may complement the original treatment. Factors influencing combination therapy decisions include not only added efficacy but also costs, side effects, adherence, and patient preferences. Sometimes the secondary effects of a drug may influence the decision to use it in a particular patient. For example, the side effect of sedation that occurs with certain medications (e.g., gabapentin or pregabalin) may be troublesome in one patient, whereas in another it may be useful to treat comorbid insomnia. The antidepressant effects of a particular adjunctive pain medication (e.g., an SNRI such as duloxetine) may reduce both pain and mood disturbances in a patient with diabetic neuropathic pain and comorbid major depressive disorder. TCAs could serve the same purpose, although higher dosages of TCAs are typically required for antidepressant action than for analgesic action, in which case the side effects of higher-dose TCAs, especially their cardiovascular effects, must be considered as well.

Selected Pain Disorders

The study and treatment of chronic pain conditions has been hindered by taxonomy and treatment guidelines based on consensus or expert opinion rather than best available evidence. In an effort to address this core problem, the American Pain Society formed a partnership with the Analgesic, Anesthetic, and Addiction Clinical Trial Translations, Innovations, Opportunities, and Networks (ACTTION) to undertake the task of creating a systematically implemented and evidence-based taxonomy for chronic pain conditions called the ACTTION-American Pain Society Pain Taxonomy (AAPT). The AAPT separates chronic pain conditions into five major systems: peripheral nervous system and CNS, musculoskeletal system, orofacial and head system, visceral/pelvic/urogenital system, and other disease-associated pain that cannot be classified elsewhere (Fillingim *et al.* 2014).

Neuropathic Pain

The two main categories of neuropathic pain are peripheral neuropathic pain and central neuropathic pain. As indicated by their names, peripheral neuropathic pain results from injury to or dysfunction of the peripheral nerves, and central neuropathic pain results from damage to or dysfunction in the CNS. Peripheral neuropathic pain is commonly caused by diabetes, autoimmune conditions, chemotherapy for cancer, trauma, inherited disorders (e.g., Charcot-Marie-Tooth disease), chronic alcohol use, and other factors. The most common etiologies for central neuropathic pain are multiple sclerosis, poststroke pain, and spinal cord injury (Watson and Sandroni 2016). Overall, chronic neuropathic pain conditions are relatively common, although the range of estimates is wide, from 1% to 17.9% in the general population in a systematic review (van Hecke *et al.* 2014).

A meta-analysis of 229 RCTs evaluating pharmacotherapy for neuropathic pain (Finnerup *et al.* 2015) showed generally modest effects on pain. One hundred twenty-seven (55%) of the 229 trials involved patients with painful diabetic polyneuropathy or postherpetic neuralgia. Pooled NNTs were 6.4 for SNRIs, mainly including duloxetine (seven of nine studies positive) and venlafaxine (two of five studies positive); 7.7 for pregabalin; 7.2 for gabapentin; and 10.6 for capsaicin high-concentration patches. NNTs were lower for TCAs, opioids, tramadol, and botulinum toxin A and were undetermined for lidocaine patches. Tolerability and safety were higher for topical drugs, and costs were lower for TCAs and tramadol. These findings led to the following:

1. A strong recommendation for TCAs, SNRIs, pregabalin, and gabapentin as first-line treatments

2. A weak recommendation for lidocaine patches, capsaicin high-concentration patches, and tramadol as second-line treatments
3. A weak recommendation for opioids and botulinum toxin A as third-line treatments

The IASP noted that "although few clinical trials have been conducted, no medications have demonstrated efficacy in patients with lumbosacral radiculopathy, which is probably the most common type of neuropathic pain" (Dworkin *et al.* 2007, p. 237). Neuropathy related to HIV and cancer chemotherapy may also be more refractory to treatment than other types of neuropathic pain. The IASP also remarked that little is known regarding the treatment response of those with mild to moderate neuropathic pain because most trials have enrolled patients with more severe neuropathic pain. Moreover, long-term effectiveness is unknown because most RCTs have been of less than 3 months' duration. The IASP also favored secondary amine TCAs (nortriptyline and desipramine) over tertiary amine TCAs (amitriptyline and imipramine) because of their comparable efficacy but fewer side effects. Finally, the IASP concluded that the magnitude of pain reduction associated with opioid analgesics is at least as great as that obtained with other treatments for neuropathic pain.

Central neuropathic pain syndromes may respond differently to pharmacotherapy. Some evidence suggests benefit from lamotrigine and amitriptyline for central poststroke pain, pregabalin and lamotrigine are favored for spinal cord injury, and duloxetine and cannabinoids show some promise for central neuropathic pain due to spinal cord injury (Watson and Sandroni 2016).

Duloxetine, venlafaxine, pregabalin, oxcarbazepine, TCAs, gabapentin, and botulinum toxin have been found to be more effective than placebo for diabetic neuropathic pain (Waldfogel *et al.* 2017; Wiffen *et al.* 2017). Combination therapy using medicines with different mechanisms of action is used clinically, but high-quality evidence supporting specific approaches is lacking.

Fibromyalgia

Mechanisms and Evaluation

Fibromyalgia is one of the most common musculoskeletal disorders seen in rheumatology practice as well as primary care. It is often classified among the functional somatic syndromes, which include irritable bowel syndrome, chronic fatigue syndrome, temporomandibular joint disorder, interstitial cystitis, and other symptom-based conditions manifested by a cluster of symptoms for which the pathophysiological mechanism is not well understood (Aaron and Buchwald 2001).

The American College of Rheumatology core diagnostic criteria for fibromyalgia, initially developed in 2010 and revised in 2016 (Wolfe and Hauser 2011; Wolfe *et al.* 2016), depend entirely on clinical history and exam and do not require any laboratory or radiological testing. According to the American College of Rheumatology, fibromyalgia may be diagnosed when *all* of the following four criteria are met:

1. Generalized pain, defined as pain in at least four of five regions, is present.
2. Symptoms have been present at a similar level for at least 3 months.
3. Widespread pain index is > 7 and symptom severity scale score is > 5, or widespread pain index is 4-6 and symptom severity scale score is > 9.
4. A diagnosis of fibromyalgia is valid irrespective of other diagnoses and does not exclude the presence of other clinically important illnesses.

Another set of criteria have been proposed as part of the AAPT with a focus on providing a practical basis for clinical work and also good diagnostic validity for trial inclusion to help reduce heterogeneity in studies, in turn aspiring to higher-yield data (Arnold *et al.* 2019). AAPT core diagnostic criteria for fibromyalgia are as follows:

1. Multisite pain defined as six or more pain sites out of a total of nine possible sites
2. Moderate to severe sleep problems *or* fatigue

3. Multisite pain plus fatigue or sleep problems present for at least 3 months

The AAPT Fibromyalgia Work Group also identified a set of common associated features that are not necessary for but may support a diagnosis of fibromyalgia. They are tenderness, dyscognition (concentration problems, forgetfulness, disorganized or slow thinking), musculoskeletal stiffness, and environmental sensitivity or intolerance.

The prevalence of fibromyalgia is estimated at between 0.5% and 12%, and the condition is more common in women than in men, at an approximately 3:1 ratio (Arnold *et al.* 2019). The prevalence rises with age around 50-59 years, then declines in older age around 80 years. The average age at onset is between 30 and 50 years, but fibromyalgia has been noted to occur in children and adolescents, with an estimated prevalence between 1% and 6.2%.

The pathogenesis of fibromyalgia is unclear, but one putative mechanism relates to a centralized pain state that could be considered a single, lifelong disease that manifests in a variety of pain states, including headaches, temporomandibular joint disorder, chronic fatigue, irritable bowel syndrome, and other regional pain syndromes that are poorly understood. A family history of chronic pain is often present. Early life adverse events, trauma, medical illness, and psychosocial stressors are risk factors for developing fibromyalgia.

The primary problem in fibromyalgia appears to be not that there is too much input coming from the pressure nociceptors peripherally but rather that there is inadequate filtering of that activity, perhaps because of decreased activity of descending anti-nociceptive pathways. In fact, multiple mechanisms seem to be operative in fibromyalgia (Abeles *et al.* 2007). Two key mechanisms are as follows:

1. Functional imaging studies in fibromyalgia patients have shown increased blood flow to pain-relevant areas of the brain at lower

thresholds of nociceptive input.

2. There appears to be dysregulation of descending inhibitory pain pathways. Thus, the pain "amplifier" is turned up and the "mute" button is turned down in fibromyalgia patients. This concept is known as *central sensitization* (Bourke *et al.* 2015).

Table 59-3 summarizes the current state of evidence on fibromyalgia.

TABLE 59-3. Evidence-based fibromyalgia treatments from three national guidelines

	Strength of recommendation[a]		
Treatment	**Canada**	**Israel**	**Germany**
Pharmacotherapy			
TCAs (e.g., amitriptyline)	A	A	B
SNRIs (duloxetine, milnacipran)	A	A	B/C
a_2d ligands (pregabalin, gabapentin)	A	A	C
Tramadol	C	B	--
SSRIs	A	--	C
Nonpharmacological therapies			
Cognitive-behavioral therapy	A	A	A
Exercise (aerobic)	A	A	A
Balneotherapy (spas, hydrotherapy)	--	C	B

Note. SNRI = serotonin-norepinephrine reuptake inhibitor; SSRI = selective serotonin reuptake inhibitor; TCA = tricyclic antidepressant; -- = not applicable.

[a] A = should be offered to most patients; B = may be offered to most patients but may not be offered to a substantial minority; C = can be offered to a minority of patients.

Low Back Pain

A systematic review by Chou *et al.* (2017) provides a comprehensive update on the evaluation and management of low back pain. Most low back pain (85%) is nonspecific--that is, it cannot be attributed to a specific disease or spinal abnormality. Classification schemes frequently conflict with one another, and there is little evidence that labeling patients by using specific anatomical diagnoses improves outcomes. In a primary care setting, low back pain is only occasionally caused by a specific serious disorder, such as cancer (0.7% of cases), compression fracture (4%), or spinal infection (0.01%). The estimated prevalence of ankylosing spondylitis in primary care patients ranges from 0.3% to 5%. Spinal stenosis and symptomatic herniated disc are present in about 3% and 4% of patients, respectively. Cauda equina syndrome, due to massive midline disc herniation, is very rare, found in 0.04% of patients with low back pain. Table 59-4 outlines some key recommendations with respect to the evaluation and management of low back pain. In the absence of red flags, a conservative approach for at least 4 weeks is usually warranted, even if sciatica is present.

TABLE 59-4. Key aspects of the evaluation and management of low back pain

Most back pain (> 70%-80%) improves in the first 2-6 weeks. Thus, a 4-week wait (i.e., a conservative approach) is warranted (even with sciatica) in the absence of red flags.

Red flags that may prompt earlier diagnostic testing or referral include the following:

* Cancer: history of cancer (strong predictor) or unexplained weight loss, failure to improve after 4 weeks, and age greater than 50 years (all weaker predictors)
* Infection (vertebral): fever, intravenous drug use, recent infection (none well studied)

Note. ESR = erythrocyte sedimentation rate; NSAID = nonsteroidal antiinflammatory drug; TCA = tricyclic antidepressant.

* Compression fracture: older age, osteoporosis, steroid use

* Cauda equina syndrome rare (0.04%), urinary retention 90% sensitive

Diagnostic tests are needed in only a minority of cases (with red flags or persistent neurological signs):

* MRI is the preferred imaging study (less radiation and better visualization of soft tissue, vertebral marrow, and the spinal canal).

* With some weaker red flags (e.g., age > 50 years), plain films and ESR may be obtained first and MRI obtained only if the findings on these tests are abnormal or symptoms persist.

Psychological factors are a stronger predictor of chronicity and functional outcomes such as disability than physical exam findings or the severity or duration of pain.

No treatment for back pain has good-quality (grade A) evidence of substantial benefit. The following have fair-quality (grade B) evidence of moderate benefit or small benefit but no significant harm, costs, or burdens:

* Pharmacotherapy: acetaminophen, NSAIDs, TCAs, tramadol/opiates, benzodiazepines

* Nonpharmacological treatments: chiropractic, acupuncture, massage, yoga, exercise, progressive relaxation, cognitive-behavioral therapy, intensive interdisciplinary rehabilitation

Note. ESR = erythrocyte sedimentation rate; NSAID = nonsteroidal antiinflammatory drug; TCA = tricyclic antidepressant.

Psychological factors are stronger predictors of low back pain treatment outcomes than either physical examination findings or the severity or duration of pain. Psychosocial factors that may predict poorer low back pain outcomes include the presence

of depression, passive coping strategies, job dissatisfaction, higher disability levels, disputed compensation claims, and somatization.

Pharmacotherapy trials for low back pain have been extensively studied, and overall limited benefit has been seen for most typical analgesics. Table 59-4 summarizes the current state of the evidence.

Osteoarthritis

Osteoarthritis is one of the most common musculoskeletal pain disorders in both primary care and specialty settings. Its prevalence typically increases with age (particularly after age 50 years), with the majority of individuals older than 65 years having at least one joint affected. Joints commonly involved in osteoarthritis include the distal and proximal interphalangeal (but not metacarpal) joints of the fingers, the base of the thumb, the knees, the hips, and the cervical and lumbar regions of the spine. The shoulder and elbow are rarely involved. The most common finding on physical examination is an increase in joint size secondary to osteophyte formation. Plain radiographs are typically the only diagnostic test required to confirm a diagnosis of osteoarthritis, which is manifested by loss of joint space and/or osteophyte formation.

Unlike with rheumatoid arthritis and other inflammatory arthritides, the structural changes in osteoarthritis are not amenable to specific disease-modifying treatments. The focus of treatment for osteoarthritis is a reduction in pain and preservation of function. NSAIDs are the mainstays of pharmacotherapy (Towheed *et al.* 2006). Although acetaminophen has traditionally been widely used to treat osteoarthritis, the evidence shows only modest benefits over placebo, and the status of acetaminophen as a first-line treatment for osteoarthritis is in question (Leopoldino *et al.* 2019).

Low-quality evidence suggests that chondroitin, either alone or in combination with glucosamine, is superior to placebo for the treatment of osteoarthritis pain in short-term studies (Singh *et al.* 2015). In contrast, hyaluronic acid seems to be effective in knee osteoarthritis, although it does require intra-articular administration. It also seems to be similar in efficacy to continuous NSAID therapy (Bannuru *et al.* 2014) and intra-articular corticosteroids (Bannuru *et al.* 2009). The long-term use of opioids for the treatment of pain related to osteoarthritis of the hip and knee confers benefits that are small at best and carries significant risks of side effects (da Costa *et al.* 2014).

In contrast to the many trials of antidepressants for neuropathic pain, fibromyalgia, and chronic low back pain, few studies have investigated antidepressants for the treatment of osteoarthritic pain. One exception is duloxetine, for which three trials in osteoarthritis have shown efficacy for pain (Pergolizzi *et al.* 2013). When depression co-occurs with arthritis, it can explain as much of the variance in pain intensity as the objective severity of the arthritis (Katon *et al.* 2007), and RCTs have shown that treating depression in arthritis patients may reduce pain as well as depression (Kroenke *et al.* 2009a; Lin *et al.* 2003). Thus, although antidepressants cannot currently be recommended as a first-line treatment for osteoarthritis patients without depression, screening for and co-managing depression may benefit pain outcomes.

Headache

Although there are less common and/or more serious causes of headache, most individuals with chronic headache have either migraine headache or tension-type headache (TTH). Up to one-third of the general population report TTH, and 10% experience migraine headaches (Robbins and Lipton 2010). Patients with migraine headache present to physicians for care more often than those with TTH. Sinus disease, hypertension, and eye strain are not common causes of headache, contrary to common lore.

Migraine is easier to diagnose in the presence of auras, which most commonly include a visual prodrome such as blind spots (scotomas), zigzag patterns (fortification spectra), or flashing lights (scintillae). However, auras occur in less than 20% of patients with migraine attacks.

Diagnostic criteria can differentiate migraine headache from TTH. Migraine without aura is diagnosed if at least two of the following are true: 1) nausea is present during the attack, 2) light sensitivity is present during the attack, and 3) some of the attack interferes with the patient's activities. TTH is diagnosed if the headache is not associated with nausea and at least two of the following are true: 1) the headache is bilateral, 2) non-pulsatile pain is present, 3) the pain is mild to moderate in intensity, and 4) the headache is not worsened by activity.

Some individuals with migraine or TTH develop chronic daily headache, defined as a headache frequency of [?] 15 days a month for longer than 3 months. A common reversible cause of chronic daily headache is medication overuse headache, which can develop when analgesics are taken for headaches more than 2-3 days per week. All analgesics have the potential for medication overuse headache, but the risk appears to be the highest with opioids or combination analgesics containing butalbital or caffeine, intermediate with triptans, and lowest with NSAIDs. Medication overuse headache often manifests as a headache that is present on awakening and that responds to analgesics with only transient relief. This can lead to a problematic cycle of increased analgesic use.

Neuroimaging is low yield in headache evaluation. Even among selected patients with headache seen in tertiary referral centers, less than 1%-2% have abnormal imaging findings that influence treatment (Clarke *et al.* 2010). Factors that may justify an imaging study are focal neurological signs or symptoms, onset of headache after age 40 years, and severe or worsening headaches that do not respond to appropriate therapy.

An initial stepped-care approach to pharmacotherapy for migraine and TTH is summarized in Table 59-5. Treatment of less common types of headache (e.g., cluster headache) or chronic refractory headache warrants referral to a neurologist or other headache specialist.

TABLE 59-5. Stepped-care pharmacotherapy for headache

Medication	**Migraine**	**Tension type**
Acute (abortive)		
Step 1	NSAID	Acetaminophen or NSAID
Step 2	Triptan	
Step 3	Opioid	

Note. NSAID = nonsteroidal antiinflammatory drug.

Algorithmic Approach to the Treatment of Chronic Pain

This chapter has focused on the main classes of treatments for chronic pain, with a particular emphasis on pharmacotherapy. Five of the most common pain disorders have been discussed: neuropathic pain, fibromyalgia, low back pain, osteoarthritis, and headache. On the basis of our reviews within these parameters, an evidence-based stepped-care algorithm for treating pain is summarized in Table 59-6. This algorithm is adapted from a previous review (Kroenke *et al.* 2009b) and was tested (in an earlier version) in a clinical trial (Kroenke *et al.* 2014).

TABLE 59-6. Evidence-based stepped-care analgesic algorithm by type of pain condition

Step	Medication	Dosing	MSK[a]	FM	NP	HA
1	**Simple analgesics**					
	Acetaminophen	650-1,000 mg every 6 h (maximum 3,000-4,000 mg/day, but only 2,000 mg/day if cirrhosis or [?] 3 alcoholic drinks/day)	+	+	+	+

Step	Medication	Dosing	MSK[a]	FM	NP	HA
	NSAIDs[b,c]					
	Naproxen	500 mg every 12 h or 500 mg in A.M. and then 250 mg bid (up to 1,000 mg/day)	+	+	+	+
	Ibuprofen	600 mg every 6 h (maximum 2,400 mg/day)	+	+	+	+
	Salsalate	1,000 mg every 8 h or 1,500 mg every 12 h (up to 3,000 mg/day)	+	+	+	+
	Meloxicam	7.5-15 mg/day (up to 15 mg/day)	+	+	+	+
	Etodolac	300 mg every 8 h or 500 mg every 12 h (maximum 1,000 mg/day)	+	+	+	+
	Diclofenac	50 mg every 8 h (maximum 150 mg/day)	+	+	+	+
	Sulindac	150-200 mg bid (maximum 400 mg/day)	+	+	+	+
2	**TCAs[b]**					
	Amitriptyline	Start at 10-25 mg/day; titrate to 100 mg/day		+	+	+-
	Nortriptyline	Start at 10-25 mg/day; titrate to 100 mg/day		+	+	+-

Step	Medication	Dosing	MSK[a]	FM	NP	HA
2	**Muscle relaxants[b]**					
	Cyclobenzaprine	5-10 mg bid to tid (maximum 20-30 mg total daily dose)	+	+-		
	Methocarbamol	Start at 500 mg qid; can increase to 1,000 mg qid	+-	+-		
	Tizanidine	Start at 2 mg tid; can increase to 6-8 mg tid				
2	**Gabapentoids**					
	Gabapentin	Start at 100 mg tid; titrate to 900-1,200 mg tid		+-	++	+-
	Pregabalin	Start at 75-100 mg bid; titrate to 450 mg/day total in twice-daily doses		++	++	
2	**SNRI antidepressants**					
	Venlafaxine	Start at 75 mg/day sustained release; titrate to 225 mg/day		+-	+-	+-
	Duloxetine	Start at 30 mg/day; titrate to 60 mg/day	+	++	++	
	Milnacipran	Start at 12.5 mg bid; titrate to 50 mg bid		++		
3	**Category IV controlled**					
	Tramadol	Start at 25 mg bid or tid; titrate to maximum 100 mg qid	+	+	+	+

Step	Medication	Dosing	MSK[a]	FM	NP	HA
4	**Category II opiates[b]**					
	Hydrocodone	Start at 5 mg bid to qid; try to keep [?] 10-20 mg qid	+-		+-	+-
	Oxycodone	Start at 5 mg bid to qid; try to keep [?] 10-20 mg qid (a sustained-release formulation is also available that can be given twice daily)	+-		+-	
	Morphine	Start at 15 mg bid sustained release; try to keep [?] 60 mg bid	+-		+-	
A	**Migraine-specific agents[b,d]**					
	Triptans[b]					
	Sumatriptan	50-100 mg oral or 5-20 mg nasal spray				+
	Zolmitriptan	2.5-5.0 mg oral or nasal spray				+
	Beta-blockers[b]					
	Propranolol	20-80 mg bid				+
	Metoprolol	25-100 mg bid				+
	Topiramate	Start at 25 mg hs to bid; titrate to 50 mg bid (or 100 mg hs)				+
	Divalproex	Start at 250 mg bid; titrate to				+

Step	Medication	Dosing	MSK[a]	FM	NP	HA
		500 mg bid				
B	**Topical analgesics**					
	Capsaicin	Apply 0.025%-0.075% cream 2-4 times/day over painful area	+		+	
	Lidocaine gel or patch	Gel or ointment 2-4 times/day or 5% patch ([?] 3 patches/day)	+		+	
	Salsalate/other NSAIDs	Apply 2-4 times/day over painful area	+		+	

Note. FM = fibromyalgia; HA = headache; MSK = musculoskeletal; NP = neuropathic; NSAID = nonsteroidal antiinflammatory drug; SNRI = serotonin-norepinephrine reuptake inhibitor; TCA = tricyclic antidepressant.

++ = FDA approved and/or strong evidence from multiple randomized controlled trials; + = moderate evidence; +- = mixed (inconclusive) evidence.

[a] Includes back pain, osteoarthritis, and other localized joint or musculoskeletal pain.

[b] This is not a list of all drugs in this class.

[c] Consider trials of at least two NSAIDs; over-the-counter = naproxen, ibuprofen, ketoprofen.

[d] Triptans used for acute migraine treatment; other drugs used for migraine prevention.

Other Issues

Treatment of Pain in the Context of Depression or Anxiety

There is substantial evidence that people with pain and depression have significantly reduced physical, mental, and social function compared with people with only pain or depression (IsHak *et al.* 2018). In particular, the presence of pain negatively affects depression outcomes, and depression in turn makes pain treatments less effective. Anxiety may have a similar effect, although the research in this area is less substantial than for depression. Several trials have shown that depression treatment also benefits patients on pain outcomes and that simultaneous treatment of comorbid depression and pain is effective (Greco *et al.* 2004; Kroenke *et al.* 2009a; Lin *et al.* 2003).

Given the high co-occurrence of pain with anxiety and depression, practitioners should screen all pain patients for symptoms of anxiety and depression. It is also prudent to identify and treat pain problems when treating anxiety or depression, as untreated pain will likely limit the improvement in psychiatric symptoms.

Antidepressant selection may be influenced by the presence of pain. TCAs and SNRIs appear to be more effective than SSRIs or other antidepressants in patients with comorbid pain.

Placebo Effect

As with other symptom-based conditions (e.g., depression, anxiety, somatoform disorders), pain has a placebo response in the range of 30%-40% or higher. This can make it challenging to separate the specific effects of a pain treatment--medication or nonpharmacological treatment--from placebo or other nonspecific effects. At the same time, placebo effects on pain outcomes can be useful in clinical practice, including in terms of patient expectancy for an analgesic outcome and the clinical benefits of a positive therapeutic relationship.

Experimental work has revealed some interesting physiological effects of placebo. A meta-analysis of 12 studies (1,183 participants) was conducted to examine the effects of placebo and an opioid antagonist, naloxone, on pain (Sauro and Greenberg 2005). Placebo administration was associated with a decrease in self-reported pain, and a hidden or blind injection of naloxone reversed placebo-induced analgesia. An experimental study in 20 healthy subjects found that placebo and nocebo effects (i.e., the therapeutic and adverse effects, respectively, of inert substances or sham procedures) are associated with opposite responses of dopaminergic and endogenous opioid neurotransmission in a distributed network of regions throughout the brain (Scott *et al.* 2008). The results support other literature showing that the belief in and expectation of analgesia induce discrete physiological changes, leading to relief from pain, and this response may be mediated by endogenous opioids.

Clinical ways to take advantage of the placebo effects of an analgesic were summarized by Klinger *et al.* (2014):

- **Enhancing expectations**--examples include 1) emphasizing positive drug effects and avoiding an overemphasis on side effects, 2) explaining the mechanism of drug action, 3) having personal interaction rather than using only written materials, and 4) explaining the course of drug action while avoiding unrealistic promises.
- **Enhancing learning components**--examples include 1) focusing on sensory aspects of a pain medicine, such as its color or size, to distinguish it from other medicines the patient may be taking; 2) associating analgesic medication with positive internal states and positive external conditions; 3) combining analgesic intake with other pain-relieving techniques; and 4) encouraging time-contingent (scheduled) rather than pain-contingent (intermittent) use of analgesics.

Gaps in the Knowledge Base Regarding the Treatment of Chronic Pain

There are several important gaps in knowledge regarding treatment that in fact are probably not unique to chronic pain. For one thing, there are few head-to-head trials, which limits our ability to compare various active treatments against each other. Few trials have evaluated different strategies for choosing initial treatment, so deciding between first-line and subsequent treatments is more a matter of expert consensus, clinician experience, and patient preferences. Evidence is sparse on the effectiveness of dual-medication or other combination therapy versus monotherapy or sequential treatment, even though patients are frequently prescribed more than one medication or treatment. Finally, most treatment trials are short, so evidence of benefits sustained beyond 4-12 weeks is often lacking. This is a critical gap when the clinical entity being investigated is defined by long-term persistence.

Despite these gaps, substantial evidence has accumulated for treating chronic pain. Avoiding ineffective treatments and maximizing the use of treatments proven beneficial in clinical trials are likely to produce better outcomes than have often been experienced by clinicians and patients in the management of chronic pain.

Conclusion

Chronic pain remains one of the most complex, prevalent, and morbid medical problems. It occurs across many medical diagnoses and may also exist in situations where the etiology of the pain is unclear. We have a wide variety of tools at our disposal to address chronic pain, including medications, surgical interventions, electrophysiological devices, lifestyle and behavioral approaches, and psychological interventions. Given the complexity of both the clinical condition of chronic pain and the interventions used to treat it, judicious use of these tools must be undertaken to achieve the best results while minimizing side effects and complications of treatment. Clearly, much remains to be discovered about how chronic pain arises and what can be done to eliminate it.

CHAPTER 60

Treatment of Child and Adolescent Disorders

Karen Dineen Wagner, M.D., Ph.D.
Steven R. Pliszka, M.D.

This chapter focuses on the use of psychopharmacology for treating psychiatric disorders in children and adolescents. It is important for clinicians to be aware of the evidence base for the use of psychotropic medications by children and adolescents. In this chapter, data from the literature, with a focus on controlled studies, are presented. On the basis of these findings, clinical recommendations regarding pharmacotherapy for childhood psychiatric disorders are offered. The appendix and tables at the end of this chapter contain specific information about dosages, monitoring, and adverse effects of psychotropic medications in pediatric patients.

Psychotropic Medication for Children and Adolescents

Evaluation

Before the initiation of psychotropic medication for children and adolescents, a comprehensive evaluation is necessary to ensure the accuracy of the diagnosis. A thorough history and careful attention to the clinical presentation are central components of the evaluation. The clinician should interview the child and parents separately so that both have the opportunity to freely express their concerns. Extended family members, school personnel, and school records are other potential sources of information.

Clinicians must be skilled at differential diagnosis of childhood psychiatric disorders, given that there is a significant overlap of symptoms between these disorders.

Knowledge of commonly occurring comorbid disorders is also necessary. Medical conditions should be considered within the differential diagnosis and adequately assessed.

Disorder-specific rating scales completed at baseline and during the course of treatment may be useful in the measurement of clinical outcome.

Clinical Issues Affecting Response to Pharmacotherapy

Whenever a child does not respond to initial pharmacotherapy, several clinical issues should be addressed before alternative or adjunctive medication is initiated.

Diagnostic Accuracy

The diagnosis should be reassessed. Often there is symptomatic overlap between disorders that may lead to misdiagnosis. For example, symptoms of excessive energy and distractibility are common features of both ADHD and bipolar disorder.

Comorbid Disorders

Unrecognized comorbid disorders may adversely affect treatment outcome. As an example, comorbid ADHD may lower response rates in the treatment of bipolar disorder (Pavuluri *et al.* 2006).

Psychosocial Factors

Child abuse, domestic violence, family conflict, parental psychopathology, and bullying by peers may lead to symptoms that mimic or exacerbate a preexisting psychiatric disorder.

Medication Compliance

Some children and adolescents are reluctant to take medication because of such reasons as denial of illness, perceived stigma, and side effects. For increased medication compliance, the child or adolescent, as well as the parents, must understand the youth's disorder, course of illness, and goals of treatment. It is important for parents to participate in monitoring their child's medication compliance.

Nonpharmacological Treatment

Psychotherapy may be beneficial, either alone or in conjunction with medication. Specific psychotherapies have been found to be effective in the treatment of some childhood disorders. For example, cognitive-behavioral therapy (CBT) and interpersonal therapy have demonstrated efficacy in the treatment of adolescents with depression (Weersing *et al.* 2017). Similarly, CBT is commonly used for the treatment of childhood anxiety disorders (Wang *et al.* 2017). Behavioral intervention has led to improvement in symptoms of ADHD for children (Coles *et al.* 2020). Family-focused therapy with medication treatment has shown benefit in the treatment of children with bipolar disorder (Miklowitz and Chung 2016). Social skills training can be a useful component of treatment in autism spectrum disorder (Dekker *et al.* 2019).

Informed Consent

Informed consent is necessary before psychotropic medication is prescribed to any patient, but it is particularly important in pediatric psychopharmacology because few medications have been approved by the FDA for young populations. There are five recommended components of informed consent for prescribing psychotropic medications to children and adolescents (Popper 1987). The child's parent(s) and the child or adolescent should be provided with the following information:

1. The purpose (benefits) of the treatment
2. A description of the treatment process
3. An explanation of the risks of the treatment, including risks that would ordinarily be described by the psychiatrist and risks that would be relevant to making the decision
4. A statement of alternative treatments, including nontreatment
5. A statement that there may be unknown risks associated with these medications (This is particularly essential for children because of the paucity of information on the potential long-term effects of psychotropic medications.)

Evidence Base

It is important for clinicians to be aware of the evidence base for medication treatment of each childhood psychiatric disorder. Clinical treatment guidelines generally rely on the strength of the available data in determining first-line agents. In most cases, clinicians should select a medication within the group of first-line agents when initiating medication treatment with a child. Additional factors that will dictate medication choice are prior medication history, medical history, side-effect profile of the drug, and adolescent and parent preferences.

Major Depressive Disorder

The lifetime prevalence of major depressive disorder (MDD) or persistent depressive disorder in adolescents is 11.7% (Merikangas *et al.* 2010). DSM-5 (American Psychiatric Association 2013) criteria are used to establish a diagnosis of MDD in children and adolescents. The mean length of an episode of MDD in youth ranges from 8 to 13 months, and relapse rates range from 30% to 70% (Birmaher *et al.* 2002). There is increasing evidence for the continuity of depression from youth into adulthood (Melvin *et al.* 2013).

Selective Serotonin Reuptake Inhibitors

For the acute and maintenance treatment of MDD in children and adolescents, the FDA has approved two selective serotonin reuptake inhibitor (SSRI) medications: fluoxetine for patients ages 8 years and older and escitalopram for patients ages 12 years and older. Other SSRIs that have been studied in controlled trials for children and adolescents with MDD include citalopram, sertraline, and paroxetine. Information about dosages, monitoring, and adverse effects of SSRIs is provided in the appendix to this chapter.

Fluoxetine

There have been three positive controlled medication trials of fluoxetine in the treatment of MDD in children and adolescents. In the first study, 96 child and adolescent

outpatients (ages 8-17 years) with MDD were randomly assigned to receive fluoxetine 20 mg/day or placebo for an 8-week trial (Emslie *et al.* 1997). The fluoxetine group, with 27 youths (56%) much or very much improved, showed statistically significantly greater improvement in Clinical Global Impression (CGI) Scale scores than the placebo group, with 16 youths (33%) much or very much improved. Medication side effects leading to discontinuation in the study were manic symptoms in three patients and severe rash in one patient.

In a double-blind, placebo-controlled multicenter study of fluoxetine, 219 child and adolescent outpatients (ages 8-17 years) with MDD were randomly assigned to fluoxetine 20 mg/day or placebo for an 8-week trial (Emslie *et al.* 2002). Improvement in depression was statistically significantly greater for the fluoxetine group, as assessed by means of the Children's Depression Rating Scale-Revised (CDRS-R), than for the placebo group. Fifty-two percent of patients treated with fluoxetine were rated as much or very much improved, compared with 37% of patients in the placebo group. Headache was the only side effect that was reported more frequently in the group treated with fluoxetine than in the placebo group.

In a multicenter trial of 439 adolescent outpatients with a diagnosis of MDD (March *et al.* 2004), patients were randomly assigned to receive 12 weeks of fluoxetine (10-40 mg/day), fluoxetine (10-40 mg/day) with CBT, CBT alone, or placebo. Compared with placebo, the combination of fluoxetine with CBT was significantly superior, according to changes in CDRS-R scores. Combination treatment with fluoxetine and CBT was significantly superior to treatment with fluoxetine alone or CBT alone. Fluoxetine monotherapy was superior to CBT. Response rates (defined as CGI ratings of much or very much improved) were 71% for fluoxetine-CBT combination therapy, 61% for fluoxetine, 43% for CBT, and 35% for placebo.

Escitalopram

There have been two controlled trials of escitalopram in the treatment of youth with depression, one positive and one negative. The efficacy of escitalopram in adolescents was demonstrated in a double-blind, placebo-controlled multicenter trial of 157 adolescents with MDD (Emslie *et al.* 2009). Patients were randomly assigned to escitalopram (dosage range = 10-20 mg/day) or placebo for an 8-week trial. The group treated with escitalopram showed statistically significantly greater improvement in depression (CDRS-R scores) than the placebo group. Sixty-four percent of escitalopram-treated patients were much or very much improved, compared with 53% of placebo-treated patients. In a study that included 264 children and adolescents with MDD (Wagner *et al.* 2006a), there was no significant difference in improvement on CDRS-R scores at endpoint between escitalopram and placebo. The most common adverse events with escitalopram were headache, abdominal pain, nausea, insomnia, and menstrual cramps.

Citalopram

There have been two controlled trials of citalopram in the treatment of depression in youth, one with positive and one with negative results. The efficacy of citalopram was demonstrated in a double-blind, placebo-controlled multicenter trial of 174 outpatient children and adolescents (ages 7-17 years) with MDD (Wagner *et al.* 2004b). Patients were randomly assigned to receive citalopram (dosage range = 20-40 mg/day; mean daily dosage = 23 mg for children, 24 mg for adolescents) or placebo for an 8-week trial. Compared with the placebo group, the citalopram group showed statistically significantly greater improvement in depression (CDRS-R scores). The most common adverse events were headache, nausea, rhinitis, abdominal pain, and influenza-like symptoms. A European double-blind, placebo-controlled multicenter study (von Knorring *et al.* 2006) of citalopram for 224 adolescents with MDD failed to show superiority of citalopram to placebo on the primary efficacy measures--the Schedule for Affective Disorders and Schizophrenia for School-Aged Children-Present Episode Version (K-SADS-P) and the Montgomery-Asberg Depression Rating Scale (MADRS). The most commonly reported adverse events were headache, nausea, and vomiting.

Sertraline

The efficacy of sertraline for MDD was evaluated in two identical double-blind, placebo-controlled multicenter studies of 376 outpatient children and adolescents (Wagner *et al.* 2003a). Patients were randomly assigned to sertraline (dosage range = 50-200 mg/day; mean daily dosage = 131 mg) or placebo for a 10-week trial. Compared with the placebo group, the group receiving sertraline showed a statistically significantly greater improvement in depression (CDRS-R scores). Response rates (decrease [?] 40% in baseline CDRS-R scores) were 69% in the group treated with sertraline and 59% in the placebo group. The most common side effects in the group treated with sertraline were headache, nausea, insomnia, upper respiratory tract infection, abdominal pain, and diarrhea.

Sertraline, CBT, and combined CBT plus sertraline were compared in the treatment of 73 adolescents with depressive disorders (Melvin *et al.* 2006). All treatments resulted in statistically significant improvement on all outcome measures; there were no significant advantages of combined treatment.

In the Adolescent Depression and Psychotherapy Trial (ADAPT [Goodyer *et al.* 2008]), 208 adolescents with MDD were randomly assigned to receive an SSRI alone or an SSRI plus CBT for 12 weeks. No significant differences were found between the groups; 44% of the SSRI-alone group and 42% of the SSRI-plus-CBT group were much or very much improved on the CGI-Improvement subscale (CGI-I).

Paroxetine

There have been three double-blind, placebo-controlled trials of paroxetine for treatment of depression in children and adolescents, all of which had negative findings on the primary outcome measure. In a study of 275 adolescent outpatients (ages 12-18 years) with MDD, patients were randomly assigned to paroxetine (dosage range = 20-40 mg/day; mean daily dosage = 28 mg), imipramine (dosage range = 200-300 mg/day; mean daily dosage = 205 mg), or placebo for an 8-week trial (Keller *et al.* 2001). There was no statistically significant difference between treatment groups on the primary efficacy measure of reduction in total score on the Hamilton Rating Scale for Depression. The most common side effects reported for paroxetine were headache, nausea, dizziness, dry mouth, and somnolence.

Two hundred six children and adolescents (ages 7-17 years) with MDD were included in an 8-week double-blind, placebo-controlled, randomized multicenter study of paroxetine treatment (Emslie *et al.* 2006). There was no statistically significant difference

between patients treated with paroxetine and those given placebo on change from baseline in CDRS-R total score at endpoint. Adverse events reported with paroxetine with an incidence greater than 5% and at least twice that with placebo were dizziness, cough, dyspepsia, and vomiting.

A 12-week international placebo-controlled multicenter trial of paroxetine in 286 adolescents with MDD failed to show superiority for paroxetine compared with placebo on change from baseline in MADRS or Schedule for Affective Disorders and Schizophrenia for School-Aged Children-Lifetime Version total score (Berard *et al.* 2006).

Other Antidepressants

Information about dosages, monitoring, and adverse effects of commonly used antidepressants are provided in the appendix to this chapter.

Venlafaxine

Two double-blind, placebo-controlled multicenter studies have evaluated the efficacy of venlafaxine extended release (XR) in the treatment of MDD in 165 and 169 child and adolescent outpatients, respectively (Emslie *et al.* 2007). Patients were randomly assigned to venlafaxine XR (37.5-225 mg/day; flexible dosage based on body weight) or placebo for 8-week trials. Both studies were negative on the primary outcome measure of change from baseline to endpoint in the CDRS-R scores. The most common adverse events with venlafaxine were anorexia and abdominal pain (Emslie *et al.* 2007).

Nefazodone

There have been two double-blind, placebo-controlled multicenter trials of nefazodone in the treatment of MDD in youth (Rynn *et al.* 2002; U.S. Food and Drug Administration 2004b). These studies failed to find statistically significant differences in improvement in baseline-to-endpoint CDRS-R scores between the nefazodone-treated group and the placebo-treated group. The most common adverse events with nefazodone were headache, abdominal pain, nausea, vomiting, somnolence, and dizziness.

Bupropion

There are no controlled trials of bupropion for the treatment of pediatric depression. In an 8-week study of bupropion sustained release (dosage range = 100-400 mg/day; mean daily dosage = 362 mg) in the treatment of

11 adolescents with MDD, 8 adolescents (79%) showed a 50% reduction in depression scores from baseline (Glod *et al.* 2000). Bupropion sustained release was assessed in an 8-week open study for the treatment of comorbid depression and ADHD in 24 adolescents (Daviss *et al.* 2001). Global improvement was reported in 14 subjects (58%) for both depression and ADHD and in 7 subjects (29%) for depression only. Common side effects were headache, nausea, rash, and irritability.

Mirtazapine

There have been two double-blind, placebo-controlled multicenter trials of mirtazapine in the treatment of child and adolescent outpatients with MDD. In these studies, mirtazapine was not superior to placebo on the primary efficacy measure of change from baseline to endpoint in CDRS-R scores (U.S. Food and Drug Administration 2004b).

Duloxetine

There have been two failed 10-week trials of duloxetine (fixed dosing, 30 mg/day and 60 mg/day; and flexible dosing, 60-120 mg/day) in the treatment of children and adolescents with MDD (Atkinson *et al.* 2014; Emslie *et al.* 2014). Duloxetine and fluoxetine were not superior to placebo on the primary efficacy measure of change from baseline to endpoint in CDRS-R scores. The most common adverse events with duloxetine were nausea, vomiting, nasopharyngitis, upper abdominal pain, headache, and somnolence.

Desvenlafaxine

The efficacy of desvenlafaxine at a low exposure (20-35 mg/day based on weight) and a higher exposure (25-50 mg/day based on weight) for the treatment of MDD in children and adolescents (ages 7-17 years) was assessed in a double-blind, placebo-controlled 8-week trial. Desvenlafaxine was not superior to placebo on the primary efficacy measure of change from baseline to week 8 in the CDRS-R total score (Atkinson *et al.* 2018). In a fluoxetine-referenced study that included 339 children and adolescents ages 7-17 years, neither desvenlafaxine (25-50 mg/day) nor fluoxetine (20 mg/day) statistically separated from placebo on the primary outcome measure of change from baseline to week 8 in CDRS-R total score (Weihs *et al.* 2018). The most common adverse events with desvenlafaxine were headache, abdominal pain, nausea, and dizziness.

Selegiline Transdermal System

In a placebo-controlled trial of 308 adolescents with MDD, selegiline transdermal system was not superior to placebo on the primary efficacy measure of change from baseline to endpoint in CDRS-R scores (DelBello *et al.* 2014). The most common adverse events for selegiline were application site reactions, headaches, and nausea.

Vilazodone

There have been two double-blind, placebo-controlled 8-week trials of vilazodone for treatment of MDD in youth (Durgam *et al.* 2018). In one trial, 529 adolescents (ages 12-17 years) were randomly assigned to vilazodone (15 mg/day), vilazodone (30 mg/day), or placebo (Durgam *et al.* 2018). There was no statistically significant difference between vilazodone (15 mg/day), vilazodone (30 mg/day), and placebo on the primary efficacy measure of change from baseline to week 8 in CDRS-R total score.

In another trial, 473 children and adolescents (ages 7-17 years) were randomly assigned to vilazodone (15 or 30 mg/day), placebo, or fluoxetine (20 mg/day) (Findling *et al.* 2020). In this failed trial, neither vilazodone nor fluoxetine was significantly superior to placebo on the primary efficacy measure of change from baseline to week 8 in the CDRS-R total score. The most common adverse events with vilazodone were nausea, headache, vomiting, diarrhea, abdominal pain, somnolence, and dizziness.

Vortioxetine

In a 6-month open-label trial, 41 youths with depressive or anxiety disorders received vortioxetine (5-20 mg/day), which showed a trend toward effectiveness (Findling *et al.* 2018).

Meta-Analysis: Pharmacological and Psychotherapeutic Treatments

A systematic review and network meta-analysis of the comparative efficacy of antidepressants, psychotherapies, and their combination for acute treatment of children and adolescents with depression included placebo-controlled and head-to-head comparison trials of 16 antidepressants, 7 psychotherapies, and 5 combinations of antidepressants and psychotherapy (Zhou *et al.* 2020). The quality of evidence was rated as low to very low. Only fluoxetine (alone or in combination with CBT) was more effective than both placebo and psychological control conditions.

Suicidality and Black Box Warning

In a combined analysis of 24 short-term placebo-controlled trials of antidepressant medications in child and adolescent MDD, OCD, or other psychiatric disorders, the rates of suicidality (suicidal thinking and behavior) were 4% for patients given medication and 2% for patients given placebo. There were no completed suicides in any of the clinical trials. The FDA directed manufacturers to add a black box warning to the health professional label of antidepressant medications to describe the increased risk of suicidal thoughts and behavior for children and adolescents being treated with antidepressant medications and to emphasize the need for close monitoring of patients taking the medications (U.S. Food and Drug Administration 2004a). Parents and patients should be advised of the black box warning for antidepressant medication.

In a subsequent meta-analysis of 27 trials of antidepressants in pediatric MDD, the rates of suicidal ideation and attempts were 3% in the youths treated with antidepressants and 2% in the youths who received placebo (Bridge *et al.* 2007). The investigators reported that the number needed to treat was 10, whereas the number needed to harm was 112, and therefore the benefits of antidepressants outweigh the potential risk from suicidal ideation or attempt. A number of studies, in both the United States and Europe, have failed to demonstrate an association between antidepressant use and youth suicide (Gibbons *et al.* 2006; Markowitz and Cuellar 2007;

Simon *et al.* 2006; Sondergard *et al.* 2006). It is noteworthy that the suicide rate in youths increased after the addition of the black box warning on antidepressants (Hamilton *et al.* 2007; Lu *et al.* 2020). The FDA advisory has been associated with significant decreases in the rates of diagnosis and treatment of pediatric depression (Libby *et al.* 2007; Lu *et al.* 2020). The risk of deliberate self-harm was found to be higher in youths whose treatment was initiated with high-dosage SSRIs than in those whose treatment began with SSRIs at modal dosages (i.e., usual or most common dosage) (Miller *et al.* 2014).

Treatment-Resistant Depression

In the National Institute of Mental Health (NIMH)-funded multisite Treatment of SSRI-Resistant Depression in Adolescents trial (Brent *et al.* 2008), 334 adolescents with SSRI-resistant depression were randomly assigned to one of four treatments for 12 weeks: switch to an alternative SSRI (paroxetine, citalopram, or fluoxetine), switch to an alternative SSRI plus CBT, switch to venlafaxine, or switch to venlafaxine plus CBT. CBT plus a medication switch (to venlafaxine or to an alternative SSRI) produced the highest rate of response (54.8%). Response rates (CGI-I score [?] 2 and CDRS-R [?] 50% reduction) were similar for switching to an alternative SSRI and switching to venlafaxine (47% and 48.2%, respectively). Skin problems and increases in diastolic blood pressure and pulse were more frequently experienced during venlafaxine treatment than during SSRI treatment.

To date, there have been no randomized controlled trials (RCTs) that investigated medication augmentation strategies for children and adolescents who do not respond to initial antidepressant medication.

There have been preliminary investigations of intravenous ketamine for treatment-resistant depression in adolescents. In an open-label study, 13 adolescents (ages 12-18 years) with treatment-resistant depression were administered 6 ketamine (0.5 mg/kg) infusions over 2 weeks. Response ([?] 50% decrease in CDRS-R) rate was 38%. Two of the five responders relapsed within 2 weeks, and the others showed sustained remission at 6 weeks (Cullen *et al.* 2018). In a randomized double-blind, single-dose crossover study, 17 adolescents (ages 13-17 years) with treatment-resistant depression were given a single infusion of ketamine (0.5 mg/kg over 40 minutes) or midazolam (0.045 mg/kg over 40 minutes) (Dwyer *et al.* 2021). Compared with midazolam, a single ketamine infusion produced a significantly greater reduction in depressive symptoms 24 hours after infusion based on improvement in the MADRS score. The most common adverse event with ketamine infusion was transient dissociative symptoms.

Clinical Recommendations for Major Depressive Disorder

SSRIs are first-line medication treatments for MDD in children and adolescents (American Academy of Child and Adolescent Psychiatry and American Psychiatric Association 2018).

An evidence-based consensus medication algorithm for the treatment of childhood MDD is available (Texas Children's Medication Algorithm Project [Hughes *et al.* 2007]). Based on research evidence and panel discussion, four stages of medication treatment are identified:

- Stage 1: SSRI
- Stage 2: Alternative SSRI
- Stage 2A (if partial response to SSRI): SSRI + lithium, bupropion, or mirtazapine
- Stage 3: Different class of antidepressant medication (venlafaxine, bupropion, mirtazapine, duloxetine) (Note: Since publication of this algorithm, there have been controlled trials of desvenlafaxine and vilazodone for children and adolescents with MDD.)
- Stage 4: Reassessment, treatment guidance

An additional recommendation is that antidepressants should be continued for 6-12 months after symptom remission. At the time of discontinuation of an antidepressant, the dosage should be tapered slowly (i.e., no more than 25% per week). The typical tapering and discontinuation period is 2-3 months.

Bipolar Disorder

The prevalence of bipolar disorder in a community sample of adolescents was found to be 1% (Merikangas *et al.* 2010). Although DSM-5 criteria are used to diagnose bipolar disorder in youths, children with bipolar disorder often exhibit mixed mania and rapid cycling (Geller *et al.* 2000). One-year recovery rates of 87% and relapse rates of 61%-80% have been reported in children and adolescents with bipolar disorder (Birmaher *et al.* 2020; B. Geller *et al.* 2004).

Six medications have FDA approval for the acute treatment of bipolar I disorder, mixed or manic episode, in youths: lithium (age [?] 7 years), aripiprazole (age [?] 10 years), asenapine (age [?] 10 years), olanzapine (age [?] 13 years), risperidone (age [?] 10 years), and quetiapine (age [?] 10 years). Ziprasidone has been studied for the treatment of bipolar disorder in youths, but it does not have FDA approval for that indication. Lithium also has FDA approval for use in the maintenance treatment of bipolar I disorder, mixed and manic episodes, in youths age 7 years or older.

Lithium

The efficacy of lithium for the treatment of bipolar I disorder, manic or mixed episode, was assessed in an 8-week double-blind, placebo-controlled trial involving 81 youths (ages 7-17 years) (Findling *et al.* 2015d). The mean lithium serum level at endpoint was 0.98 mEq/L. Lithium was superior to placebo on the primary outcome measure of change in Young Mania Rating Scale (YMRS) score from baseline to endpoint. On CGI-I scores, 47% of lithium-treated and 21% of placebo-treated patients were much or very much improved. The most common adverse events with lithium were vomiting, nausea, and headache. There was a statistically significant increase in thyrotropin concentration with lithium. Information on the dosing and monitoring of lithium and a discussion of side effects can be found in the appendix to this chapter.

In an NIMH-funded study, 153 children and adolescents with bipolar I disorder, mixed or manic episode, were randomly assigned to treatment with lithium, divalproex, or placebo in an 8-week trial (Kowatch *et al.* 2007). Target lithium serum levels were 0.8-1.2 mEq/L. Lithium was not significantly superior to placebo.

In a small double-blind, placebo-controlled study of lithium treatment for adolescent bipolar disorder and DSM-III-R (American Psychiatric Association 1987)-defined substance dependence (Geller *et al.* 1998), 25 adolescent outpatients were randomly assigned to either lithium (mean serum level = 0.97 mEq/L) or placebo for a 6-week trial. There was significantly greater improvement in global functioning with lithium than with placebo. Side effects in the group treated with lithium were polyuria, thirst, nausea, vomiting, and dizziness.

Atypical Antipsychotics

Information about dosages, monitoring, and adverse effects of atypical antipsychotics is provided in the appendix to this chapter.

Aripiprazole

The efficacy of aripiprazole was assessed in a 4-week double-blind, placebo-controlled trial that included 296 youths (ages 10-17 years) with bipolar I disorder, mixed or manic episode (Findling *et al.* 2009). Both low-dosage aripiprazole (10 mg/day) and high-dosage aripiprazole (30 mg/day) were significantly superior to placebo in reduction of YMRS scores. The response rate ([?] 50% reduction in YMRS score) was 44.8% for low-dosage aripiprazole, 63.6% for high-dosage aripiprazole, and 26.1% for placebo. The most common adverse events with aripiprazole were somnolence, extrapyramidal side effects (EPS), and tremor, which were more common in the high-dosage aripiprazole group. In a 26-week placebo-controlled extension phase, both aripiprazole 10 mg and 30 mg were significantly superior to placebo (Findling *et al.* 2013c).

Asenapine

The efficacy of asenapine was evaluated in a 3-week double-blind, placebo-controlled trial of 403 youths (ages 10-17 years) with bipolar I disorder, mixed or manic episode (Findling *et al.* 2015b). Dosages ranged from 2.5 to 10 mg twice daily. Asenapine was significantly superior to placebo on the outcome measure of change in YMRS from baseline to endpoint. The most comment adverse events were somnolence, dizziness, oral hypoesthesia, headache, fatigue, and increased appetite.

Olanzapine

There is one reported double-blind, placebo-controlled multicenter study of olanzapine (2.5-20 mg/day) in the treatment of adolescent outpatients with bipolar I disorder, mixed or manic episode (Tohen *et al.* 2007). Adolescents were randomly assigned to receive olanzapine ($n = 107$) or placebo ($n = 54$) for 3 weeks. Response rates (defined as [?] 50% decrease in YMRS score) were significantly greater for the olanzapine group (44.8%) than for the placebo group (18.5%). Remission rates (defined as YMRS score < 12) were also significantly greater for the olanzapine group (35.2%) than for the placebo group (11.1%). Adverse effects in the olanzapine group were hyperprolactinemia, weight gain (mean = 3.7 kg), somnolence, and sedation.

Risperidone

In a 3-week double-blind, placebo-controlled trial, the efficacy of risperidone was assessed in 169 children and adolescents (ages 10-17 years) with bipolar I disorder, manic or mixed episode (Haas *et al.* 2009a). Both low-dosage risperidone (0.5-2.5 mg/day) and high-dosage risperidone (3-6 mg/day) were significantly superior to placebo in reduction of YMRS scores. The response rate ([?] 50% reduction in baseline YMRS score) was 59% for low-dosage risperidone and 63% for high-dosage risperidone, compared with a placebo response rate of 26%. The most common adverse events with risperidone were somnolence, headache, and fatigue. EPS were more common in the high-dosage risperidone group than in the low-dosage group.

Quetiapine

In a 3-week double-blind, placebo-controlled trial, the efficacy of quetiapine was assessed in 277 youths (ages 10-17 years) with bipolar I disorder, manic or mixed episode (Pathak *et al.* 2013). Both low-dosage quetiapine (400 mg/day) and high-dosage quetiapine (600 mg/day) were significantly superior to placebo in reduction of YMRS scores. The response rate ([?] 50% reduction in baseline YMRS score) was 55% for low-dosage quetiapine, 56% for high-dosage quetiapine, and 28% for placebo. The most common adverse events with quetiapine were somnolence, sedation, dizziness, and headache.

Ziprasidone

The efficacy of ziprasidone was assessed in a 4-week double-blind, placebo-controlled trial that included 237 youths (ages 10-17 years) with bipolar I disorder, manic or mixed episode (Findling *et al.* 2013b). Ziprasidone dosages ranged from 40 to 160 mg/day. Ziprasidone was significantly superior to placebo in reduction of YMRS scores. A [?] 50% reduction in YMRS scores was achieved by 53% of the ziprasidone-treated group and 22% of the placebo group. The most common side effects with ziprasidone were sedation, somnolence, headache, fatigue, and nausea.

Mood Stabilizers

Information about dosages, monitoring, and adverse effects of mood stabilizers is provided in the appendix to this chapter.

Divalproex

A 4-week double-blind, placebo-controlled multicenter trial of 150 youths (ages 10-17 years) with bipolar I disorder, mixed or manic episode, did not show a significant difference in reduction in YMRS scores from baseline to endpoint between patients given divalproex extended release (ER) and those given placebo (Wagner *et al.* 2009). The mean modal dose of divalproex ER was 1,286 mg. There were no statistically significant differences in adverse-event incidence between the divalproex ER and placebo groups. Gastrointestinal symptoms were more commonly reported with divalproex ER than with placebo.

Carbamazepine

In an open-label study of carbamazepine ER in 137 youths (ages 10-17 years) with bipolar I disorder, mixed or manic episode, there was a statistically significant reduction in scores on the YMRS from baseline to endpoint (Findling and Ginsberg 2014). At endpoint, the most prevalent dosage of carbamazepine ER was 1,200 mg/day. The most common adverse events were rash, decreased white blood cell count, nausea, and vomiting.

Oxcarbazepine

In a double-blind, placebo-controlled multicenter trial of oxcarbazepine for the treatment of children and adolescents (ages 7-12 years) with bipolar I disorder, mixed or manic episode, 116 youths received oxcarbazepine (mean dosage = 1,515 mg/day) or placebo for a 7-week trial (Wagner *et al.* 2006b). There was no significant difference in reduction in YMRS scores at endpoint between the oxcarbazepine and placebo groups. The most common side effects in the oxcarbazepine-treated patients were dizziness, nausea, somnolence, diplopia, fatigue, and rash.

Topiramate

A double-blind, randomized, placebo-controlled multicenter study assessing the efficacy of topiramate treatment in children and adolescents with acute mania was designed as a 200-patient study but was terminated after random assignment of 56 patients (ages 6-17 years) when adult mania trials did not show efficacy (DelBello *et al.* 2005). Dosages were titrated to 400 mg/day (mean dosage = 278 mg/day). Over a 4-week period, no significant difference was found between the topiramate and placebo groups. The most common adverse events in the topiramate group included decreased appetite, nausea, diarrhea, paresthesias, and somnolence.

Lamotrigine

In a 12-week open-label trial, the efficacy of lamotrigine was assessed in 30 children and adolescents with bipolar spectrum disorders (Biederman *et al.* 2010). The mean lamotrigine dosage at endpoint was 160.7 mg/day. Significant improvement in mean YMRS scores was reported; however, only about half the participants completed the trial, and seven participants discontinued lamotrigine because of rash.

Comparator Studies

The Treatment of Early Age Mania study compared the effectiveness of risperidone, lithium, and divalproex in the treatment of 279 youths (ages 6-15 years) with bipolar I disorder, manic or mixed episode (Geller *et al.* 2012). Response was defined as a CGI-Bipolar Disorder-Improvement Mania score of 2 or lower. The mean lithium serum level was 1.09 mEq/L, the mean divalproex level was 113.6 mg/mL, and the mean risperidone dosage was 2.57 mg/day. The risperidone response rate (68.5%) was significantly higher than response rates for lithium (35.6%) and divalproex (24%). There was no significant difference between lithium and divalproex response rates. Increased weight gain, BMI, and prolactin levels were significantly more common with risperidone than with lithium or divalproex. There were also higher response rates for nonresponders who switched to risperidone and partial responders augmented with risperidone than for lithium and divalproex (Walkup *et al.* 2015).

Similarly, a comparator analysis of the efficacy of antipsychotics and mood stabilizers for the treatment of pediatric bipolar disorder showed significantly greater improvement in YMRS scores for patients given antipsychotics than for those given mood stabilizers (Correll *et al.* 2010). Effect sizes were 0.65 for antipsychotics and 0.24 for mood stabilizers.

The comparative efficacy of lithium, divalproex, and carbamazepine was assessed in a 6-week randomized open-label trial involving 42 children and adolescents with bipolar disorder (Kowatch *et al.* 2000b). There were no significant differences in response rates ([?] 50% reduction in YMRS score) among the groups given lithium (38%), divalproex (53%), and carbamazepine (38%).

The comparative efficacy of risperidone and divalproex was assessed in an 8-week double-blind, randomized trial of 66 children and adolescents with bipolar disorder (Pavuluri *et al.* 2010). A significantly higher response rate ([?] 50% reduction in YMRS) was found for risperidone (78.1%) than for divalproex (45.5%), and improvement was more rapid in risperidone-treated patients than in divalproex-treated patients.

The comparative efficacy of quetiapine and divalproex was assessed in a 4-week double-blind, placebo-controlled trial involving 50 adolescents with bipolar I disorder, manic or mixed episode (DelBello *et al.* 2006). No significant group differences were found in reduction in YMRS scores during the trial.

In an 8-week open-label trial, the efficacies of olanzapine and risperidone were compared in preschool-age children with bipolar disorder (Biederman *et al.* 2005). There were no significant differences in response rates between risperidone (69%) and olanzapine (53%).

In a 6-week placebo-controlled trial of valproic acid versus risperidone for children (ages 3-7 years) with bipolar disorder, manic, mixed, or hypomanic episode, risperidone was superior to placebo on reduction in YMRS scores from baseline to endpoint. No significant difference was found between valproic acid and placebo (Kowatch *et al.* 2015).

Combination Treatment

Some children with bipolar disorder may not respond to initial monotherapy treatment or may need combination treatment over the course of the illness. For example, in a study by Kowatch *et al.* (2000a), after acute 6-week treatment with one mood stabilizer, 20 of 35 youths (58%) needed additional psychotropic medication over the next 16 weeks. The response rate to combination treatment with two mood stabilizers was high (80%) for youths who did not respond to monotherapy.

The FDA has approved the use of quetiapine or aripiprazole as an adjunct to lithium or valproate treatment in children ages 10 years and older with bipolar I disorder, mixed or manic episode.

The effectiveness of combination treatment with lithium and divalproex was assessed in an open trial (Findling *et al.* 2003). Ninety youths (ages 5-17 years) with bipolar I or II disorder were treated for up to 20 weeks with divalproex (mean blood level = 79.8 mg/mL) and lithium (mean blood level = 0.9 mmol/L). The clinical remission rate (defined as contiguous weekly ratings of YMRS scores [?] 12.5, CDRS-R scores [?] 40, Children's Global Assessment Scale scores [?] 51, clinical stability, and no mood cycling) was 42%.

The efficacy of risperidone in combination with lithium or divalproex was assessed in a 6-month open-label trial (Pavuluri *et al.* 2004). Thirty-seven youths (ages 5-18 years) with bipolar I disorder, manic or mixed episode, received either risperidone (mean dosage = 0.75 mg/day) plus divalproex (mean serum level = 106 mg/mL) or risperidone (mean dosage = 0.70 mg/day) plus lithium (mean serum level = 0.9 mEq/L). Response rates ([?] 50% reduction in baseline YMRS scores) were similar for both combinations: 80% for divalproex plus risperidone and 82.4% for lithium plus risperidone. There were no significant differences between the groups in safety and tolerability.

Risperidone augmentation for lithium nonresponders was assessed in a 1-year open-label study (Pavuluri *et al.* 2006). Twenty-one of 38 youths (ages 4-17 years) who did not respond to lithium monotherapy or relapsed after initial response were given risperidone (mean dosage = 0.99 mg/day) for 11 months. The response rate in the lithium plus risperidone group was 85.7%.

In a double-blind, placebo-controlled study of quetiapine, 30 adolescents with bipolar disorder received divalproex (20 mg/kg) and were randomly assigned to adjunctive quetiapine (mean daily dosage = 432 mg) or placebo for 6 weeks (DelBello *et al.* 2002). The response rate ([?] 50% reduction in baseline YMRS score) was significantly higher in the group receiving divalproex and quetiapine (87%) than in the group receiving divalproex and placebo (53%).

No significant differences were found between lithium plus risperidone and lithium plus quetiapine in reduction in YMRS scores for 30 youths hospitalized for a manic or mixed episode (Habibi *et al.* 2017).

Celecoxib adjunctive to lithium and risperidone was assessed in an 8-week double-blind, placebo-controlled trial in 42 adolescents with bipolar I disorder, manic episode (Mousavi *et al.* 2017). Significantly greater improvement in YMRS scores was found for the celecoxib group than for the placebo group. The researchers suggested that the mood-stabilizing role of celecoxib might be through its action on inflammatory cascades.

Maintenance Treatment

Clinical outcomes with lithium compared with other mood stabilizer medications were evaluated in a longitudinal study of 340 youths (ages 7 years to 17 years, 11 months) with DSM-IV (American Psychiatric Association 1994)-defined bipolar disorder I, II, or not otherwise specified over a 10-year period (Hafeman *et al.* 2020). The lithium group had significantly fewer suicide attempts, fewer depressive symptoms, less psychosocial impairment, and less aggression.

Lithium in the maintenance treatment of bipolar I disorder, mixed or manic, has been assessed in a randomized, double-blind, placebo-controlled discontinuation study of youths ages 7 to 17 years (Findling *et al.* 2019). Responders to lithium treatment from one of two previous multiphase studies received up to 28 weeks of either continued lithium treatment (mean lithium dosage 1,394 mg/day at start of discontinuation trial) or placebo. Youths who continued lithium treatment (*n* = 17) had a significantly lower hazard ratio (0.28) compared with those in the placebo group (*n* = 15). Most study discontinuations were due to mood symptom exacerbations, particularly in the placebo group.

There have been two maintenance studies of aripiprazole for treatment of bipolar disorder in youths. A 72-week double-blind, placebo-controlled maintenance study of aripiprazole in children (ages 4-9 years) with bipolar I, II, or not otherwise specified showed that time to discontinuation due to a mood event was significantly longer in the aripiprazole group than the placebo group (Findling *et al.* 2012b). In a randomized double-blind 30-week placebo-controlled trial of aripiprazole for maintenance treatment in bipolar I disorder, manic or mixed, in youth ages 10-17 years, both dosages of aripiprazole (10 mg/day and 30 mg/day) showed significantly greater improvement in YMRS total score compared with placebo during the 26-week extension phase (Findling *et al.* 2013c).

Sixty youths who had responded to a combination of lithium and divalproex in a 20-week trial were randomly assigned in a double-blind trial to either lithium or divalproex for 18 months (Findling *et al.* 2005). There was no significant difference in the time to relapse between the groups (median days: divalproex 112, lithium 114).

Lamotrigine efficacy for maintenance treatment of pediatric bipolar disorder has been assessed in two trials. In a 14-week open-label trial that included 46 youths (ages 8-18 years) with mania or hypomania, lamotrigine improved depressive and manic symptoms (Pavuluri *et al.* 2009). Adjunctive maintenance lamotrigine for bipolar disorder in 10-to 17-year-olds was evaluated in a placebo-controlled randomized withdrawal study. There were no significant differences between the lamotrigine group and the placebo group in the time to occurrence of a bipolar event (Findling *et al.* 2015a).

Bipolar Depression

Two medications have FDA approval for bipolar I disorder, major depressive episode: lurasidone (age [?] 10 years) and olanzapine/fluoxetine combination (age [?] 10 years).

Lurasidone

The efficacy of lurasidone for 347 children and adolescents ages 10-17 years with bipolar I disorder, major depressive episode, was assessed in a double-blind, placebo-controlled 6-week trial (DelBello *et al.* 2017). Lurasidone dosage range was 20-80 mg/day. There was a statistically significantly greater improvement in CDRS-R total score for the lurasidone group compared with the placebo group. The most common adverse events with lurasidone were nausea and somnolence.

A post hoc analysis of this trial showed that lurasidone was efficacious for youths with bipolar depression with mixed (subsyndromal hypomania) features (Singh *et al.* 2020).

Olanzapine/Fluoxetine Combination

Two hundred twenty-five youths (ages 10-17 years) with bipolar I disorder, major depressive episode, were randomly assigned to olanzapine/fluoxetine combination (OFC; dosage range 3 mg olanzapine/25 mg fluoxetine to 12/50 mg/day) or placebo in an 8-week double-blind randomized trial (Detke *et al.* 2015). OFC-treated patients had significantly greater changes in CDRS total score from baseline to week 8. The most common adverse events with OFC were weight gain, increased appetite, and somnolence, as well as hyperlipidemia.

Quetiapine

Quetiapine XR was not significantly superior to placebo in an 8-week double-blind, placebo-controlled trial of 193 youths (ages 10-17 years) with bipolar I disorder, major depressive episode (Findling *et al.* 2014). Similarly, a double-blind, placebo-controlled pilot study of treatment of adolescents with bipolar I disorder, major depressive episode, did not show statistically significant differences between quetiapine and placebo from baseline to endpoint on CDRS-R total scores (DelBello *et al.* 2009).

Lithium

To date, there are no controlled studies of lithium for the treatment of bipolar I disorder, major depressive episode, in youths. An open-label study showed improvement in depressive symptoms (Patel *et al.* 2006).

Lamotrigine

To date, there are no controlled studies of lamotrigine for the treatment of bipolar I disorder, major depressive episode, in youths. Open-label studies have shown some effectiveness, with improvement in depressive symptoms (Biederman *et al.* 2010; Chang *et al.* 2006).

Clinical Recommendations for Bipolar Disorder

Treatment guidelines were developed by expert consensus and review of the available treatment literature for children and adolescents (ages 6-17 years) with bipolar I disorder, manic or mixed episode (Kowatch *et al.* 2005). Six stages were identified:

- Stage 1: Monotherapy with mood stabilizer or atypical antipsychotic
- Stage 2: Switch monotherapy agent (drug class not tried in stage 1)
- Stage 3: Switch monotherapy agent (drug class not tried in stage 1 or 2) OR combination treatment (two agents)
- Stage 4: Combination treatment (with two agents) OR combination treatment (with three agents)
- Stage 5: Alternative monotherapy (drugs not tried in stages 1, 2, or 3)
- Stage 6: Electroconvulsive therapy (adolescents) or clozapine

If a child does not respond to treatment in one stage, the clinician should move to the next stage of treatment. For treatment of bipolar I disorder, manic or mixed episode

with psychosis, the recommendation for initial treatment is a mood stabilizer plus an atypical antipsychotic. A minimum of 4 weeks at therapeutic blood levels or adequate dosages for each medication is recommended. After sustained remission of at least 12 months, medication taper should be considered.

Anxiety Disorders

DSM-5 anxiety disorders include generalized anxiety disorder, social anxiety disorder, panic disorder, selective mutism, agoraphobia, specific phobia, and separation anxiety disorder. OCD and PTSD are now in separate DSM-5 categories (Obsessive-Compulsive and Related Disorders and Trauma-and Stressor-Related Disorders, respectively).

Generalized Anxiety Disorder

The lifetime prevalence of generalized anxiety disorder (GAD) in adolescents is reported to be 2.2% (Merikangas *et al.* 2010). Children with GAD have excessive anxiety and worry about several events or activities (e.g., school performance), have difficulty controlling the worry, and have at least one associated symptom, such as restlessness, fatigue, concentration difficulties, irritability, muscle tension, or sleep disturbance (American Psychiatric Association 2013). The course of GAD in youths tends to be persistent (Kessler *et al.* 2012).

Duloxetine

Duloxetine has been approved by the FDA for the treatment of GAD in youths ages 7-17 years. The efficacy of duloxetine was assessed in a 10-week double-blind, placebo-controlled trial for 272 youths (ages 7-17 years) with GAD (Strawn *et al.* 2015a). Duloxetine was flexibly dosed from 30 to 120 mg/day. The primary efficacy measure was the Pediatric Anxiety Rating Scale (PARS). Duloxetine was significantly superior to placebo on improvement in PARS scores from baseline to endpoint. Response (defined as 50% improvement in PARS severity for GAD) and remission (defined as PARS severity score for GAD [?] 8) were significantly greater for the duloxetine group (59% and 50%, respectively) than the placebo group (42% and 34%, respectively). Adverse events reported with significantly greater frequency for the duloxetine group than for the placebo group were nausea, vomiting, decreased appetite, oropharyngeal pain, dizziness, cough, and palpitations.

Venlafaxine

The efficacy of venlafaxine XR for children and adolescents with GAD ($N = 320$) was evaluated in two double-blind, placebo-controlled trials (Rynn *et al.* 2007). Venlafaxine was given at dosages up to 225 mg/day. In one study, venlafaxine XR was superior to placebo on primary and secondary measures; however, in the other study, the results were negative.

Sertraline

Twenty-two children and adolescents (ages 5-17 years) with GAD were randomly assigned to sertraline or placebo in a 9-week double-blind trial (Rynn *et al.* 2001). The maximum dosage of sertraline was 50 mg/day. Significant differences in favor of sertraline over placebo were observed on the Hamilton Anxiety Scale scores and on CGI Severity of Illness (CGI-S) and CGI-I ratings. Side effects found to be more common (but not statistically significantly so) with sertraline than with placebo were dry mouth, drowsiness, leg spasm, and restlessness.

Escitalopram

The efficacy of escitalopram for the treatment of GAD in 51 adolescents (ages 12-17 years) was investigated in a double-blind, placebo-controlled 8-week trial (Strawn *et al.* 2020). Escitalopram dosages ranged from 15 mg/day to 20 mg/day. Escitalopram was significantly superior to placebo in reduction of anxiety symptoms.

Buspirone

There have been two unpublished randomized placebo-controlled trials of buspirone in young patients (ages 6-17 years) with GAD (U.S. Food and Drug Administration 1998, 2000). A Bayesian approach for the reanalysis of the summary data was performed (Strawn *et al.* 2018a). In the flexibly dosed ($N = 227$) and fixed-dose ($N = 341$) trials, buspirone did not separate from placebo on the outcome measure of improvement in the sum of the Columbia Schedule for Affective Disorders and Schizophrenia GAD items. Dosages ranged from 15 mg/day to 60 mg/day. Light-headedness occurred more frequently in the buspirone group than in the placebo group.

Social Anxiety Disorder

The prevalence of social anxiety disorder in adolescents is reported to be 9.1% (Merikangas *et al.* 2010). The DSM-5 diagnostic criteria for social anxiety disorder are the same for children and adolescents as for adults.

Social anxiety disorder in youth is a chronic condition, and it increases the risk of depression (Stein *et al.* 2001).

Selective Serotonin Reuptake Inhibitors

Paroxetine. The efficacy and safety of paroxetine were evaluated in a 16-week double-blind, placebo-controlled multicenter trial of 322 outpatient children and adolescents (ages 8-17 years) with social anxiety disorder (Wagner *et al.* 2004a). Paroxetine was significantly superior to placebo, with rates of response (defined as CGI-I score = 1 or 2) of 77.6% and 38.3%, respectively. Side effects more common with paroxetine than with placebo were insomnia, decreased appetite, and vomiting.

Fluoxetine. The efficacy of fluoxetine was evaluated in a 12-week randomized trial of fluoxetine (up to 40 mg/day), psychotherapy (Social Effectiveness Therapy for Children), or placebo in 80 youths (ages 7-17 years) with social anxiety disorder (Beidel *et al.* 2007). Both fluoxetine and Social Effectiveness Therapy for Children were superior to placebo in reducing social stress and behavioral avoidance and increasing general functioning.

Sertraline. Fourteen outpatient children and adolescents (ages 10-17 years) with a diagnosis of social anxiety disorder received sertraline (dosage range = 100-200 mg/day; mean daily dosage = 123 mg) in an 8-week open trial (Compton *et al.* 2001). Five of the patients (36%) were much or very much improved, and four of the patients (29%) had a partial response by the end of the 8-week trial. Sertraline was well tolerated, and no patient developed significant behavioral disinhibition or mania (Compton *et al.* 2001).

Escitalopram. Twenty children with social anxiety disorder participated in a 12-week open-label study of escitalopram (Isolan *et al.* 2007). Sixty-five percent of participants were much or very much improved.

Citalopram. Chavira and Stein (2002) investigated the effectiveness of a combined psychoeducational and pharmacological treatment program for youths with social anxiety disorder. Twelve children and adolescents (ages

8-17 years) with social anxiety disorder received citalopram (mean daily dosage = 35 mg) and eight 15-minute counseling sessions over a 12-week period. On the basis of clinical global ratings of change, five of the patients (41.7%) were very much improved, and five of the patients (41.7%) were much improved.

Venlafaxine

In a 16-week double-blind, placebo-controlled trial, 293 children and adolescents with social anxiety disorder were randomly assigned to venlafaxine XR (dosage range = 37.5-225 mg/day) or placebo (March *et al.* 2007). Venlafaxine XR was significantly superior to placebo in reducing ratings of social anxiety. Response rates (CGI-I score [?] 2) were 56% for the venlafaxine XR group and 37% for the placebo group.

Panic Disorder

The lifetime prevalence of panic disorder in adolescents is reported to be 2.3%. The DSM-5 diagnostic criteria for panic disorder in children and adolescents are the same as those for adults. Panic disorder in youths is a chronic condition, and there is continuity between pediatric and adult panic disorder (Biederman *et al.* 1997).

Selective Serotonin Reuptake Inhibitors

In an open-label trial, 12 children and adolescents (ages 7-17 years) with panic disorder were treated with an SSRI for 6-8 weeks (Renaud *et al.* 1999). Mean daily dosages of SSRIs were fluoxetine 34 mg, paroxetine 20 mg, and sertraline 125 mg. Adjunctive benzodiazepines were used for 8 patients. Seventy-five percent of patients showed much to very much clinical improvement while receiving treatment with SSRIs. At the end of the trial, 8 patients (67%) no longer fulfilled panic disorder criteria.

Paroxetine. A chart review was conducted of 18 child and adolescent outpatients (ages 7-16 years) with a diagnosis of panic disorder who received monotherapy with paroxetine (dosage range = 10-40 mg/day; mean daily dosage = 23 mg) (Masi *et al.* 2001). The mean paroxetine treatment duration was 11.7 months. Fifteen patients (83%) had a CGI-I score of much or very much improved. The most common side effects were nausea, tension, agitation, sedation, insomnia, palpitations, and headache.

Citalopram. Three youths (ages 9, 13, and 16 years) with panic disorder and school phobia were treated with citalopram (up to 20 mg/day) over an 8-to 15-month period. All patients experienced resolution of panic attacks during the course of citalopram treatment (Lepola *et al.* 1996).

Benzodiazepines

In a 2-week open trial, four adolescents with panic disorder were treated with clonazepam (0.5 mg twice daily). A significant reduction in panic attacks (from 3 attacks per week to 0.25 per week) was reported (Kutcher and MacKenzie 1988).

Mixed Anxiety Disorders

Selective Serotonin Reuptake Inhibitors

Fluvoxamine. One hundred twenty-eight outpatient children and adolescents (ages 6-17 years) with GAD, social anxiety disorder, or separation anxiety disorder (who had received 3 weeks of open treatment with supportive psychoeducational therapy without improvement) were randomly assigned to fluvoxamine (up to 300 mg/day) or placebo for an 8-week trial (Research Unit on Pediatric Psychopharmacology Anxiety Study Group 2001). The group treated with fluvoxamine had a significantly greater reduction in PARS scores than did the placebo group. The response rate (CGI-I score [?] 3) was 76% in the group being treated with fluvoxamine and 29% in the group receiving placebo. After completion of the 8-week placebo-controlled study, the 128 patients entered a 6-month open-label treatment phase in which fluvoxamine responders continued on fluvoxamine, fluvoxamine nonresponders were switched to fluoxetine, and placebo nonresponders were switched to fluvoxamine (Walkup *et al.* 2002). Anxiety symptoms remained low in 33 of the 35 subjects (94%) who initially responded to fluvoxamine. Of 14 fluvoxamine nonresponders switched to fluoxetine, anxiety symptoms significantly improved in 10 patients (71%). Among 48 placebo nonresponders, 27 (56%) showed significant improvement in anxiety on fluvoxamine.

Fluoxetine. Seventy-four youths (ages 7-17 years) with GAD, separation anxiety disorder, or DSM-IV-defined social phobia (i.e., DSM-5 social anxiety disorder) were randomly assigned to fluoxetine (20 mg/day) or placebo for 12 weeks (Birmaher *et al.* 2003). Sixty-one percent of fluoxetine-treated patients and 35% of placebo-treated patients were much or very much improved.

Fluoxetine's efficacy in long-term treatment of children with GAD, separation anxiety disorder, and DSM-IV social phobia was assessed in a 1-year open treatment (Clark *et al.* 2005) following the acute-phase study described above (Birmaher *et al.* 2003). Compared with youths taking no medication, those taking fluoxetine (*n* = 42) showed significantly superior outcomes on anxiety measures.

The comparative efficacy of fluoxetine and clomipramine was evaluated in a 12-week double-blind, randomized, placebo-controlled trial for 36 youths (ages 7-17 years) with GAD, separation anxiety, or social anxiety disorder (da Costa *et al.* 2013). Although all groups showed significant improvement, no significant difference was found between fluoxetine and placebo or between clomipramine and placebo.

Sertraline. The comparative efficacy of sertraline, CBT, sertraline plus CBT, and placebo was evaluated in a 12-week RCT (the Child Anxiety Multimodal Study) involving 488 children and adolescents with a diagnosis of GAD, separation anxiety disorder, or DSM-IV social phobia (Walkup *et al.* 2008). Combination treatment was significantly superior to sertraline alone and CBT alone. Rates of response (CGI-I score [?] 2) were 80.7% for combined treatment, 59.7% for CBT, and 54.9% for sertraline. All treatments were significantly superior to placebo (23.7%).

Long-term outcomes from the Child Anxiety Multimodal Study have been reported (Piacentini *et al.* 2014). At 24 and 36 weeks, most ([?] 80%) of the acute responders maintained a positive response. Combination treatment maintained an advantage over CBT alone and sertraline alone. A 4-to 12-year follow-up showed that about 22% of youths were in stable remission, 30% were chronically ill, and 48% relapsed (Ginsburg *et al.* 2018). Treatment type was not associated with remission status.

Guanfacine.

Extended-release guanfacine was assessed for the treatment of GAD, separation anxiety disorder, and social anxiety disorder in youths ages 6-17 years (Strawn *et al.* 2017). Youths received flexibly dosed (1-6 mg/day, *n* = 62) guanfacine extended release or placebo (*n* = 21) for 12 weeks. No differences were found between the treatment groups on PARS and Screen for Child Anxiety Related Emotional Disorders scores.

Meta-Analyses: Pharmacological and Psychotherapeutic Treatments

A systematic review and meta-analysis of RCTs of SSRIs and serotonin-norepinephrine reuptake inhibitors (SNRIs) in youths with anxiety disorders (including 1,673 participants and six medications) demonstrated efficacy and moderate effect size (Cohen's *d* = 0.62), with effect size correlated with serotonergic specificity of the agent (Strawn *et al.* 2015b).

A meta-analysis of data from nine randomized, parallel group, placebo-controlled antidepressant trials (SSRIs, five trials; SNRIs, four trials) for pediatric anxiety disorders (GAD, separation anxiety disorders, and social anxiety disorder) showed that antidepressant-related improvement occurred early in treatment, and SSRIs had more rapid and greater improvement than SNRIs (Strawn *et al.* 2018b).

A systematic review of the effectiveness of CBT and pharmacotherapy in randomized and nonrandomized comparative studies for pediatric anxiety disorders (GAD, separation anxiety disorder, social anxiety disorder, specific phobias, and panic disorder) showed SSRIs and CBT to be most effective in reducing childhood anxiety symptoms; SNRIs also appear to be effective, but the evidence was less consistent (Wang *et al.* 2017). A network meta-analysis of double-blind, placebo-controlled trials of pharmacotherapy for pediatric anxiety disorders (GAD, social anxiety disorder, and separation anxiety disorder) found that only SSRIs were superior in reducing anxiety and in likelihood of treatment response compared with placebo (OR = 4.6) (Dobson *et al.* 2019). SNRIs and a_2-agonist treatment were associated with more frequent treatment response than placebo. The likelihood of treatment response was greater for SSRIs compared with SNRIs (OR = 1.9).

Clinical Recommendations for Anxiety Disorders

The American Academy of Child and Adolescent Psychiatry (AACAP) developed Clinical Practice Guidelines for Treatment of Children and Adolescents with Anxiety Disorders (Walter *et al.* 2020). With regard to medication, AACAP recommends that SSRIs be offered to patients ages 6-18 years with social anxiety, generalized anxiety, separation anxiety, or panic disorder. Clinically significant improvement in anxiety symptoms by week 6 and maximal improvement by week 12 or later has been shown with SSRIs (Strawn *et al.* 2018b).

AACAP suggests that SNRIs also can be offered to patients ages 6-18 years with social anxiety, generalized anxiety, separation anxiety, or panic disorder. In regard to duration of treatment with antidepressants for anxiety disorders, it is generally recommended that medications be maintained at an effective tolerated dosage for approximately 12 months after remission.

Obsessive-Compulsive Disorder

OCD has a prevalence rate of 2%-4% in youths (Douglass *et al.* 1995; Zohar 1999). The DSM-5 criteria for OCD are the same in children and adults. Pooled remission rates averaging 62% in long-term follow-ups have been reported (Liu *et al.* 2021).

Serotonin Reuptake Inhibitors

Four medications have received FDA approval for the treatment of OCD in children and adolescents: sertraline (age [?] 6 years), fluoxetine (age [?] 7

years), fluvoxamine (age [?] 7 years), and clomipramine (age [?] 10 years). Citalopram and paroxetine have been studied for treatment of OCD in youths but do not have FDA approval. Information about dosages, monitoring, and adverse effects of serotonin reuptake inhibitors is provided in the appendix to this chapter.

Sertraline

In a double-blind, placebo-controlled multicenter study, 187 children and adolescents (ages 6-17 years) with OCD were randomly assigned to sertraline or placebo (March *et al.* 1998). Sertraline dosages were titrated to a maximum of 200 mg/day during the first 4 weeks of the trial, and these dosages were maintained for an additional 8 weeks. The mean dosage of sertraline was 167 mg/day at endpoint. Compared with patients receiving placebo, patients receiving sertraline showed significantly greater improvement on the Children's Yale-Brown Obsessive Compulsive Scale (CY-BOCS), the NIMH Global Obsessive Compulsive Rating Scale, and the CGI-S and CGI-I subscales. Forty-two percent of patients in the sertraline group and 26% of patients in the placebo group were rated as very much or much improved. Side effects of insomnia, nausea, agitation, and tremor occurred significantly more often in the group receiving sertraline than in the group receiving placebo.

In an assessment of the long-term safety and effectiveness of sertraline for pediatric OCD, 137 patients who completed the 12-week double-blind, placebo-controlled sertraline study (March *et al.* 1998) were given open-label sertraline (mean dosage = 120 mg/day) in a 52-week extension study. Significant improvement was found on CY-BOCS, NIMH Global Obsessive Compulsive Rating Scale, and CGI scores. Rates of response (defined as > 25% decrease in CY-BOCS and a CGI-I score of 1 or 2) were 72% for children and 61% for adolescents (Cook *et al.* 2001). Full remission (defined as a CY-BOCS score < 8) was achieved in 47% of patients, and an additional 25% achieved partial remission (CY-BOCS score > 8 but < 15) (Wagner *et al.* 2003b). The most common side effects were headache, nausea, diarrhea, somnolence, abdominal pain, hyperkinesias, nervousness, dyspepsia, and vomiting.

The relative and combined efficacies of sertraline and CBT were assessed in a 12-week trial for 112 children and adolescents (ages 7-17 years) with OCD (Pediatric OCD Treatment Study [POTS] Team 2004). Patients were randomly assigned to sertraline, CBT, combined sertraline and CBT, or placebo. Combined treatment was significantly superior to CBT alone and sertraline alone, which did not differ from each other.

The efficacy of sequential sertraline and CBT compared with CBT and placebo was assessed in an 18-week trial for 47 youths (ages 7-17 years) with OCD (Storch *et al.* 2013). No significant difference was found between the groups on improvement in OCD symptoms.

Fluoxetine

A small double-blind crossover trial of fluoxetine and placebo in 14 children and adolescents (ages 8-15 years) with OCD was conducted (Riddle *et al.* 1992). After 8 weeks, CY-BOCS total score decreased significantly more in the fluoxetine group than in the placebo group (44% vs. 27%).

The safety and efficacy of fluoxetine were assessed in a 13-week double-blind, placebo-controlled multicenter trial (Geller *et al.* 2001). One hundred three children and adolescents (ages 7-17 years) with OCD were randomly assigned in a 2:1 ratio to either fluoxetine (dosage range = 10-60 mg/day; mean daily dosage = 24.6 mg) or placebo. The group treated with fluoxetine showed a statistically significantly greater reduction in OCD severity compared with the placebo group, as determined by changes in CY-BOCS scores. Rates of response (defined as > 40% reduction in CY-BOCS score) were 49% in the fluoxetine group and 25% in the placebo group. There were no significant differences in treatment-emergent adverse events between the fluoxetine and placebo groups.

Fluoxetine was compared with placebo in a controlled trial of 43 children and adolescents with OCD (Liebowitz *et al.* 2002). After 16 (but not 8) weeks of treatment, the fluoxetine group had significantly lower CY-BOCS scores than the placebo group.

Fluvoxamine

The safety and efficacy of fluvoxamine were evaluated in a double-blind, placebo-controlled multicenter study (Riddle *et al.* 2001). One hundred twenty outpatient children and adolescents (ages 8-17 years) with OCD were randomly assigned to receive fluvoxamine (dosage range = 50-200 mg/day; mean daily dosage = 165 mg) or placebo for a 10-week trial. Patients who did not respond after 6 weeks could discontinue the double-blind phase and enter an open-label trial of fluvoxamine. Mean scores on the CY-BOCS were significantly different for the fluvoxamine and placebo groups at weeks 1, 2, 3, 4, 6, and 10. Response rates (> 25% reduction in CY-BOCS scores) were 42% in the fluvoxamine group and 26% in the placebo group. Adverse events occurring at a placebo-adjusted frequency of greater than 10% were insomnia and asthenia.

Clomipramine

Clomipramine has been shown to be efficacious in the treatment of pediatric OCD in two double-blind, placebo-controlled trials. In the first study (Flament *et al.* 1985), 19 children (ages 10-18 years) with OCD were randomly assigned to clomipramine (dosage range = 100-200 mg/day; mean daily dosage = 141 mg) or placebo for 5 weeks. Significant improvement in observed and self-reported obsessions and compulsions was found for patients who received clomipramine. The most common side effects with clomipramine were tremor, dry mouth, dizziness, and constipation. One patient had a grand mal seizure.

In an 8-week double-blind, placebo-controlled multicenter study of 60 children and adolescents (ages 10-17 years) with OCD, it was found that patients who received clomipramine (up to 200 mg/day) had significantly greater reductions in scores on the

CY-BOCS than the placebo group (37% and 8%, respectively). Forty-seven patients continued in a 1-year open-label extension trial, and effectiveness was maintained with long-term treatment. The most common side effects with clomipramine were dry mouth, somnolence, dizziness, fatigue, tremor, headache, constipation, and anorexia (DeVeaugh-Geiss *et al.* 1992).

Citalopram

The efficacy of citalopram compared with fluoxetine was assessed for 29 children and adolescents (ages 7-18 years) with OCD in a 6-week RCT (Alaghband-Rad and Hakimshooshtary 2009). Both the citalopram and fluoxetine groups showed significant improvement from baseline on CY-BOCS, and there was no significant difference in efficacy between groups.

Twenty-three child and adolescent outpatients (ages 9-18 years) with OCD were given open-label citalopram (dosage range = 10-40 mg/day; mean daily dosage = 37 mg) in a 10-week trial (Thomsen 1997). There was a statistically significant improvement in CY-BOCS scores from baseline to endpoint. Adverse effects were minimal and transient.

In an 8-week open-label citalopram study of 15 youths (ages 6-17 years) with OCD, 14 patients showed significant improvement in CY-BOCS scores from baseline to endpoint (Mukaddes and Abali 2003).

In a long-term open study of 30 adolescents with OCD, citalopram (dosage range = 20-70 mg/day; mean daily dosage = 46.5 mg) was administered for 1-2 years (Thomsen *et al.* 2001). There was a significant reduction in CY-BOCS scores from baseline to assessment at 2 years. No serious adverse events were reported, and the most common side effects were sedation, sexual dysfunction, and weight gain.

Paroxetine

The efficacy and safety of paroxetine were assessed in a double-blind, placebo-controlled multicenter study of 203 outpatient children and adolescents (ages 7-17 years) with OCD (D. A. Geller *et al.* 2004). Patients were randomly assigned to paroxetine (dosage range = 10-50 mg/day; mean daily dosage = 23 mg) or placebo for a 10-week trial. There was a statistically significantly greater reduction in CY-BOCS scores from baseline to endpoint in patients treated with paroxetine than in patients treated with placebo. Response rates (> 25% reduction in CY-BOCS scores) were 64.9% in the paroxetine-treated patients and 41.2% in the placebo-treated patients. The most common adverse effects in the paroxetine group were headache, abdominal pain, nausea, respiratory disorder, somnolence, hyperkinesias, and trauma.

Atypical Antipsychotic Augmentation

Adjunctive risperidone ([?] 2 mg daily) was investigated in an open trial for 17 adolescents with OCD who did not respond to two serotonin reuptake inhibitor monotherapy trials. A significant reduction in CY-BOCS scores was reported (Thomsen 2004).

Aripiprazole augmentation of CBT was found to be effective in the case of an adolescent who had a partial response to combined CBT and sertraline (Storch *et al.* 2008). In a naturalistic sample of 220 children and adolescents with OCD, 43 children were treated with an atypical antipsychotic as an augmenting agent (Masi *et al.* 2009). Twenty-five of these youths (58.1%) responded to treatment.

The efficacy of aripiprazole augmentation of an SSRI was assessed in 39 youths with OCD who had not responded to two trials with SSRI monotherapy (Masi *et al.* 2010). Fifty-nine percent of the youths responded to treatment.

Other Agents

D-Cycloserine

Augmentation of CBT with D-cycloserine has been evaluated in three controlled trials with mixed results. D-Cycloserine augmentation of CBT was evaluated in a double-blind, placebo-controlled trial for 30 youths (ages 8-17 years) with OCD. No significant differences were found between treatment groups (Storch *et al.* 2010).

In a placebo-controlled randomized trial, 142 children and adolescents (ages 7-19 years) with OCD were randomly assigned to D-cycloserine plus CBT or placebo plus CBT (Storch *et al.* 2016). There were no additional benefits from D-cycloserine augmentation of CBT.

D-Cycloserine-augmented CBT was assessed in a double-blind, placebo-controlled pilot trial in 17 youths with difficult-to-treat OCD (Farrell *et al.* 2013). The augmented CBT resulted in greater improvement in OCD symptoms than CBT plus placebo.

Riluzole

Sixty children and adolescents with treatment-resistant OCD participated in a 12-week double-blind, placebo-controlled trial of add-on riluzole or placebo with current treatment (Grant *et al.* 2014). The riluzole final dosage was 100 mg/day. All participants significantly improved on CY-BOCS ratings, and there was no significant difference between riluzole and placebo on any outcome measure. Adverse events reported for patients given riluzole included one case of pancreatitis and five instances of slight increases in transaminases.

N-Acetylcysteine

N-acetylcysteine (NAC) augmentation of stable psychiatric treatment (both medication and therapy) was evaluated in a pilot double-blind, placebo-controlled 12-week trial in children and adolescents (ages 8-17 years) with OCD (Li *et al.* 2020). NAC dosages were up to 2,700 mg/day. Enrollment was stopped at 11 children out of 12 planned due to poor recruitment and study medication expiration. NAC was associated with a significant reduction in CY-BOCS total scores compared with placebo.

Meta-Analyses: Pharmacological Treatments

A systematic review of SSRIs for the treatment of OCD in children and adolescents included 12 RCTs with a total of 958 participants (Kotapati *et al.* 2019). SSRIs were shown to be superior to placebo, but effect sizes were small (standardized mean difference [SMD] = -0.43). In a different meta-analysis of pharmacological treatments for children and adolescents with OCD, the effect size for comparison of SSRIs with placebo was 0.51 (Ost *et al.* 2016).

A systematic review and meta-analysis of SSRIs and clomipramine that included nine RCTs involving 801 children and adolescents with OCD showed that the greatest benefit for SSRIs and clomipramine occurred early in treatment and that clomipramine had greater efficacy versus placebo than did SSRIs (Varigonda *et al.* 2016).

A systematic review and meta-analysis of fluoxetine in acute treatment of children and adolescents with OCD that included 188 participants in three RCTs of fluoxetine versus placebo and one RCT of fluoxetine versus citalopram was conducted (Maneeton *et al.* 2020). Fluoxetine was associated with significantly greater reduction in OCD severity, as measured by CY-BOCS, NIMH Obsessive Compulsive Scale, and CGI-S scores compared with placebo, although sample sizes were small.

Clinical Recommendations for Obsessive-Compulsive Disorder

SSRIs are the medication treatment of choice for OCD in children and adolescents (American Academy of Child and Adolescent Psychiatry 2012). Clomipramine is also effective in the treatment of this disorder; however, it is not a first-line treatment because of its adverse-event profile. A 12-week trial at an adequate dosage is indicated to determine whether a child with OCD will respond to an SSRI. If a child does not respond to one SSRI, switching to another SSRI is a reasonable strategy. Clomipramine, either as monotherapy or as augmentation of an SSRI, may be a third treatment option. Other possible SSRI augmentation strategies are clonazepam and atypical antipsychotics; however, these agents have not received systematic study. Some pediatric patients may need long-term medication maintenance; however, it is reasonable to attempt medication discontinuation 1 year after symptom stabilization. Medication should be tapered gradually to assess for relapse. Two or three relapses should lead to long-term treatment.

Posttraumatic Stress Disorder

The prevalence of PTSD in adolescents is reported to be 5% (Merikangas *et al.* 2010). The criteria for diagnosing PTSD in children older than age 6 years are the same as those used for adults (American Psychiatric Association 2013). PTSD symptoms in children tend to vary over time, and although the disorder is chronic, the course is prolonged with greater severity of the stressor (Clarke *et al.* 1993).

Selective Serotonin Reuptake Inhibitors

Sertraline

The efficacy of sertraline was evaluated in a 10-week double-blind, placebo-controlled trial of 131 children and adolescents with PTSD (Robb *et al.* 2010). Sertraline dosages ranged from 50 to 200 mg/day. There was no difference between sertraline-treated patients and placebo-treated patients in scores on the primary outcome measure, the University of California at Los Angeles Posttraumatic Stress Disorder Reaction Index for DSM-IV.

The benefit of adding sertraline versus placebo to trauma-focused CBT was assessed in a controlled 12-week trial (Cohen *et al.* 2007). Although both groups showed significant improvement in symptoms of PTSD, there was no significant advantage from adding sertraline rather than placebo to CBT.

Citalopram

Eight adolescents with PTSD received citalopram in a fixed daily dosage of 20 mg in a 12-week open-label study (Seedat *et al.* 2001). Core PTSD symptoms of reexperiencing, avoidance, and hyperarousal showed statistically significant improvement at week 12, with a 38% reduction in total score on the Clinician-Administered PTSD Scale-Child and Adolescent Version. Citalopram was well tolerated, and the most common side effects were increased sweating, nausea, headache, and tiredness.

In a larger 8-week open trial, Seedat *et al.* (2002) treated 24 children and adolescents with citalopram (dosage range = 20-40 mg/day; mean daily dosage = 20 mg). Both children and adolescents had a significant reduction in Clinician-Administered PTSD Scale-Child and Adolescent Version scores at endpoint. Common side effects of citalopram were drowsiness, headache, nausea, and increased sweating.

Alpha-2 Agonists

Guanfacine

The effectiveness of guanfacine extended release (XR) was assessed in an 8-week open-label trial for 19 youths (ages 6-18 years) with current traumatic stress symptoms (Connor *et al.* 2013). Guanfacine XR dosages ranged from 1 to 4 mg/day. On parent report, symptom clusters of reexperiencing, avoidance, and overarousal significantly improved.

Clonidine

Seven preschool children (ages 3-6 years) with a diagnosis of PTSD received open treatment with clonidine at a dosage range of 0.05-0.15 mg/day (Harmon and Riggs 1996). To decrease sedation, oral clonidine was subsequently converted to a clonidine patch. The majority of children showed at least moderate improvements in hyperarousal, hypervigilance, insomnia, nightmares, and mood lability.

Other Agents

Carbamazepine

Twenty-eight children and adolescents (ages 8-17 years) with a diagnosis of PTSD received carbamazepine (dosage range = 300-1,200 mg/day) for an average of 35 days. Twenty-two patients (78%) became asymptomatic, and the remaining six patients were significantly improved during the course of treatment (Looff *et al.* 1995).

Propranolol

The efficacy of propranolol initiated within 12 hours after emergency department admission in preventing PTSD in 29 injured youths was assessed in a 10-day double-blind, placebo-controlled trial (Nugent *et al.* 2010). There was no significant difference between the propranolol and placebo groups in PTSD symptoms at 6 weeks.

Eleven children (ages 6-12 years) with a diagnosis of PTSD participated in an off-on-off medication design of 4 weeks of propranolol treatment (Famularo *et al.* 1988). Propranolol was initiated at 0.8 mg/kg/day and titrated to a maximum of 2.5 mg/kg/day. A significant improvement in PTSD symptoms was found during the treatment period. Side effects included sedation and mildly lowered blood pressure and pulse.

Prazosin

A systematic review of prazosin in children and adolescents with PTSD included nine published articles, of which six were case reports. These case reports described improvement in patients receiving prazosin, with dosages ranging from 1 to 4 mg/day (Akinsanya *et al.* 2017).

D-Cycloserine

In a controlled trial, 57 youths (ages 7-18 years) with PTSD were randomly assigned to receive D-cycloserine and CBT or placebo and CBT (Scheeringa and Weems 2014). Although both groups had significant reductions in PTSD symptoms, there was no significant difference between the groups.

Risperidone

In case reports and a small open-label trial, risperidone has shown some benefit in reducing symptoms of PTSD in children and adolescents (Horrigan and Barnhill 1997; Keeshin and Strawn 2009; Meighen *et al.* 2007).

Quetiapine

In a case series, six adolescents with PTSD reported improvement in symptoms after 6 weeks of low-dosage (50-200 mg/day) quetiapine (Stathis *et al.* 2005).

Meta-Analysis: Psychological and Pharmacological Treatments

A meta-analysis of the efficacy of psychological and psychopharmacological treatment for PTSD in children and adolescents included 41 RCTs (39 psychological treatments, 2 psychopharmacological treatments) (Morina *et al.* 2016). Psychological interventions were found to be effective in treating PTSD, but there was very little evidence to support pharmacological treatment for PTSD in children and adolescents.

Clinical Recommendations for Posttraumatic Stress Disorder

To date, there are no FDA-approved medications for the treatment of children and adolescents with PTSD. The AACAP recommends considering SSRIs for pharmacological treatment of PTSD in children and adolescents. Other possible medications for PTSD are a- and b-adrenergic blocking agents, non-SSRI antidepressants, and mood-stabilizing agents (Cohen *et al.* 2010).

Attention-Deficit/Hyperactivity Disorder

The prevalence of ADHD in children and adolescents is estimated to range from 5% to 12%, whereas about 4% of adults in the general population meet criteria for ADHD (Kessler *et al.* 2006). In addition to demonstrating the core behavioral features of inattention, hyperactivity, and impulsivity, children with ADHD often have significant impairment in social and academic functioning (Barkley 2005). Of all of the childhood psychiatric disorders, ADHD has the greatest number of pharmacological treatment studies.

Psychostimulants

Stimulants have been used in child psychiatry for more than eight decades (Bradley 1937). Since the 1960s there have been hundreds of studies examining the effects of stimulants in children with ADHD; recently a major systematic review and network meta-analysis of double-blind, placebo-controlled trials of psychostimulants and other ADHD medications was published (Cortese *et al.* 2018). This meta-analysis examined effect sizes for both efficacy and side effects relative to placebo along with the 95% CI. In children and adolescents, the SMD for efficacy relative to placebo (based on clinician ratings) for amphetamine was -1.02 (95% CI: -1.19 to 0.85), and that of methylphenidate was -0.78 (95% CI: -0.93 to -0.62). Ratings of adverse events versus placebo significantly favored methylphenidate over amphetamine, leading the authors to suggest that methylphenidate was the preferred psychostimulant in children, but initial use of amphetamine remains appropriate.

Attention has turned to the study of potential long-term benefits of stimulant treatment of ADHD. It is not practical or ethical to do long-term placebo-controlled studies of ADHD medications. Increasingly, so-called big data studies can tie prescription of stimulants to other events in large databases, such as suicide rates, accidents, or arrests. These allow investigators to assess the impact of treatment over time. Relative to periods off medication (almost always stimulants), patients with ADHD on medication have fewer motor vehicle accidents (Chang *et al.* 2017) and traumatic brain injuries (Liao *et al.* 2018), are less likely to engage in criminal activity (Lichtenstein *et al.* 2012), and have lower rates of suicidal behavior (S. H. Liang *et al.* 2018) and substance abuse (Quinn *et al.* 2017).

The appendix at the end of this chapter shows the recommended dosage ranges for psychostimulants. The appendix also discusses adverse events, particularly growth suppression, that can occur with these medications.

Atomoxetine

Atomoxetine is a noradrenergic reuptake inhibitor that has indirect effects on dopamine reuptake in the cortex but not in the striatum (Bymaster *et al.* 2002). Numerous double-blind, placebo-controlled trials have demonstrated the medication's efficacy in the treatment of ADHD in children, adolescents, and adults (Michelson *et al.* 2001, 2002, 2003).

Atomoxetine is effective in treating ADHD in patients with comorbid tics and may also reduce tics (Allen *et al.* 2005). It is also useful for children with ADHD who have comorbid anxiety, showing effectiveness in treating anxiety and inattention (Sumner *et al.* 2005). Data from 13 (6 double-blind, 7 open-label) atomoxetine studies were pooled for youths (ages 12-18 years) with ADHD (Wilens *et al.* 2006). Of the 601 atomoxetine-treated subjects in this meta-analysis, 537 (89.4%) completed 3 months of acute treatment. At the time of the article's publication, 259 subjects (48.4%) were continuing atomoxetine treatment; 219 of these subjects had completed at least 2 years of treatment. Symptoms remained improved for up to 24 months without dosage escalation. During the 2-year treatment period, 99 subjects (16.5%) discontinued treatment due to lack of effectiveness, and 31 subjects (5.2%) discontinued treatment due to adverse events. No clinically significant abnormalities in height, weight, blood pressure, pulse, mean laboratory values, or electrocardiography parameters were found in atomoxetine-treated subjects.

Information about dosages, monitoring, and adverse effects of atomoxetine is provided in the appendix to this chapter.

Alpha-2 Adrenergic Receptor Agonists

Clonidine and guanfacine are both agonists at the a_2 receptor, which is found both presynaptically and postsynaptically in the brain. Activation of these receptors may underlie the therapeutic action of these agents in ADHD (Gamo *et al.* 2010). Guanfacine activates presynaptic a adrenoceptors 10 times more selectively than clonidine; guanfacine has an alpha a_2/a_1 receptor selectivity ratio 25 times higher than that of clonidine (Seedat 1985). As a result, clonidine is more potent than guanfacine and has a higher rate of inducing sedation. Hirota *et al.* (2014) performed a meta-analysis of all the placebo-controlled trials of clonidine and guanfacine in the treatment of ADHD.

Immediate-release clonidine was the subject of three trials involving 212 subjects. The mean dosage was 0.24 mg/day. In all three trials, clonidine was superior to placebo in reducing ADHD symptoms. Clonidine extended release was evaluated in a trial of 236 subjects at a mean dosage of 0.3 mg/day, and again clonidine was superior to placebo. Although guanfacine immediate release is commonly used in clinical practice, Hirota *et al.* (2014) found only one controlled study of its effects in ADHD; this study had only 34 participants, but guanfacine was found to be superior to placebo. In contrast, guanfacine XR has been studied in four double-blind, placebo-controlled studies involving more than 1,000 participants. The dosage range in the four studies was 2.5 to 3 mg/day, and all four studies showed guanfacine XR to be superior to placebo.

Hirota *et al.* (2014) combined all of the studies of clonidine and guanfacine to calculate the SMD of the a agonists versus placebo to be -0.59 for ADHD symptoms and -0.44 for symptoms of oppositional defiant disorder (ODD). Thus, the effect size of the a agonists is about one-half that of the psychostimulants.

Both clonidine (Kollins *et al.* 2011) and guanfacine (Wilens *et al.* 2012) have been studied as adjunctive treatments to psychostimulants for ADHD. These studies recruited participants with ADHD who had only a partial response to psychostimulants. Either an a_2 agonist or placebo was then added to the participants' stable psychostimulant dosage for several weeks in a double-blind fashion. In both studies, addition of the a agonist led to greater reduction in ADHD symptoms than addition of placebo. In a placebo-controlled comparison of dexmethylphenidate, guanfacine, and the two agents combined, the combination was superior to either agent alone in the treatment of ADHD (McCracken *et al.* 2016).

Information on the dosing of a_2 agonists and a discussion of side effects can be found in the appendix to this chapter.

Viloxazine

Viloxazine is a specific norepinephrine reuptake inhibitor, but in vivo studies in rodents (C. Yu *et al.* 2020) found that it increases serotonin, norepinephrine, and dopamine levels in the prefrontal cortex but does not increase dopamine in the nucleus accumbens, suggesting minimal abuse potential. C. Yu *et al.* (2020) also found that in vitro, viloxazine had antagonistic activity at serotonin type 2B receptors and agonistic activity at serotonin type 2C receptors, although the clinical relevance of this finding is not known.

An extended-release form of viloxazine was recently approved by the FDA for the treatment of ADHD. A randomized, double-blind, placebo-controlled 6-week trial assessed the efficacy and safety of once-daily 100 and 200 mg viloxazine in the treatment of ADHD in 477 male and female children 6-11 years of age (Nasser *et al.* 2020). At the end of the study, both dosages were superior to placebo in reducing symptoms on the ADHD Rating Scale-5.

Subsequently, Nasser *et al.* (2021) published a Phase III double-blind study of 200 and 400 mg of extended-release viloxazine versus placebo in 313 children ages 6-11 years diagnosed with ADHD. After 8 weeks, the change from baseline in the ADHD Rating Scale-5 was significantly greater in both the 200-and 400-mg groups compared with the placebo group. The 200-mg group separated from placebo at week 2, and both dosage groups separated from the placebo group at weeks 5-8.

Information on the dosing and side effects of viloxazine is provided in the appendix at the end of this chapter.

Clinical Recommendations for Attention-Deficit/Hyperactivity Disorder

Selection of an agent to treat ADHD should be based on the needs of the individual patient and family preference. Based on the strength of clinical trial data, stimulants have the largest effect size for the treatment of ADHD and are often the first agents used, but either atomoxetine, guanfacine, or viloxazine can also be used. Because of its sedating effect, clonidine is used only when the above agents have failed. Substantial numbers of patients have only a partial response to psychostimulants; multiple studies have shown that adding an a_2 agonist to the psychostimulant is an effective way to achieve a greater reduction in ADHD symptoms.

Disruptive Behavior Disorders, Mood Lability, and Aggression

ODD and conduct disorder are highly comorbid with ADHD, particularly in younger children (Pliszka 2009). DSM-5 added the diagnosis of disruptive mood dysregulation disorder (DMDD) in the Depressive Disorders category of the manual. Children with DMDD show chronically irritable mood combined with frequent outbursts of verbal and physical aggression. Children with DMDD may not meet criteria for bipolar disorder, but they may meet criteria for MDD. Psychopharmacological studies have looked at groups of children (principally with ADHD) who show high levels of aggression as a symptom, as well as those with diagnoses of DMDD. Treatments for ADHD have been used to target ODD and conduct disorder, whereas mood stabilizers and antipsychotics have been used for patients with severe aggressive outbursts, regardless of diagnosis (Pappadopulos *et al.* 2006).

ADHD With Aggression

Psychostimulants and Behavior Treatment Alone

In a meta-analysis of the literature from 1970 to 2001 that examined 28 studies to determine the effect size for stimulants on overt and covert aggression-related behaviors in children with ADHD, it was found that the mean effect size for aggressive behaviors was similar to that for core behaviors of ADHD (Connor *et al.* 2002). Two major studies (Aman *et al.* 2014; Blader *et al.* 2021) showed that adding parent training to psychostimulants can significantly reduce aggression in children with ADHD.

Combining Psychostimulants With Alpha-2 Agonists

Children (ages 6-14 years) with ADHD currently taking methylphenidate were randomly assigned to receive clonidine syrup 0.10-0.20 mg/day (*n* =

37) or placebo (*n* = 29) for 6 weeks (Hazell and Stuart 2003). Analysis showed that significantly more clonidine-treated children than control subjects were responders on the Conduct subscale (21 of 37 vs. 6 of 29; $P < 0.01$) of the parent-report Conners Behavior Checklist but not on the Hyperactive Index subscale (13 of 37 vs. 5 of 29). Compared with placebo, clonidine was associated with a greater reduction in systolic blood pressure measured standing and with transient sedation and dizziness. Clonidine-treated children had a greater reduction in a number of unwanted effects associated with psychostimulant treatment compared with placebo. The findings supported the use of clonidine in combination with psychostimulant medication to reduce conduct symptoms associated with ADHD.

Although no studies have specifically examined the effect of guanfacine on aggression in children with ADHD, controlled trials of guanfacine have shown that it clearly reduces symptoms of ODD (Hirota *et al.* 2014), and thus it is common practice to combine guanfacine with psychostimulants to treat aggression in children and adolescents with ADHD.

Combining Psychostimulants With Antipsychotics or Mood Stabilizers

Aman *et al.* (2014) tested the efficacy of adding risperidone to concurrent psychostimulant treatment and parent training (PT) in behavior management in children with ADHD and severe comorbid aggression. Children ages 6-12 years (mean age 8.89 years) with severe physical aggression were randomly assigned to a 9-week trial of PT, stimulant, and placebo (basic treatment; *n* = 84) or of PT, stimulant, and risperidone (augmented treatment; *n* = 84). Children received a psychostimulant for 3 weeks, titrated for optimal effect, while parents received PT. If there was room for improvement at the end of week 3, placebo or risperidone was added for an additional 3 weeks. Both groups showed substantial reductions in aggressive behavior during the first 3 weeks of stimulant plus PT treatment. In the second phase, the risperidone group showed significantly greater reduction in rating scale measures of aggressive behavior, but CGI-I scores did not discriminate the groups. Adverse events were as expected, with the risperidone group experiencing greater weight gain and increases in serum lipid and prolactin levels than the placebo group.

Blader *et al.* (2009) treated 74 children with ADHD and aggression with open stimulant treatment during a lead-in phase that averaged 5 weeks. Children whose aggressive behavior persisted at the conclusion of the lead-in phase (*n* = 30) were randomly assigned to receive double-blind, flexibly dosed divalproex or a placebo adjunctive to stimulant for 8 weeks. Families received weekly behavioral therapy throughout the trial. A significantly higher proportion of the children randomly assigned to divalproex met remission criteria (8 of 14; 57%) than of those randomly assigned to placebo (2 of 13; 15%).

Blader *et al.* (2021) enrolled 151 children ages 6-12 years with ADHD and significant aggressive behavior in an open, systematically titrated stimulant trial. Afterward, participants who showed an inadequate reduction in aggressive behavior were randomly assigned to receive adjunctive risperidone, divalproex, or placebo under double-blind conditions for 8 weeks. Family-based behavioral treatment was offered throughout the trial. Aggression remitted among 96 (63%) of the participants in the first phase of the trial, and among the remaining participants, 45 were then randomly assigned to receive adjunctive risperidone, divalproex, or placebo. Both the risperidone and divalproex groups showed significantly greater reductions in aggression than the placebo group; those in the risperidone group showed the greatest weight gain.

Treating Aggression Without ADHD

In the following older studies, meeting criteria for ADHD was not a requirement for study entry, and there was no psychostimulant treatment before the agent for aggression was administered.

Lithium

The efficacy of lithium in the treatment of aggression in youths with CD has been demonstrated in three double-blind, placebo-controlled inpatient studies (Campbell *et al.* 1984, 1995; Malone *et al.* 2000). In these studies, lithium was titrated to serum levels of 1-1.2 mEq/L. Lithium was superior to placebo in all three studies, with the most common lithium side effects being stomach ache, nausea, vomiting, headache, tremor, and urinary frequency.

Divalproex

Steiner *et al.* (2003) randomly assigned 71 adolescents with conduct disorder in a residential facility for juvenile offenders to two groups, which received either a therapeutic dosage or a low dosage of divalproex for 7 weeks; both subjects and outcome raters were blind to treatment status. Reduction in aggression severity, improvement in impulse control, and global improvement were greater in the group with therapeutic divalproex levels than in the low-dosage condition.

Disruptive Mood Dysregulation Disorder

Although the above studies probably included participants with DMDD, only a few treatment studies have enrolled participants who specifically met criteria for this disorder. Dickstein *et al.* (2009) studied the effect of lithium in youths (ages 7-17 years) with severe mood dysregulation who were tapered off their medications. Those who continued to have significant mood dysregulation after a 2-week single-blind placebo run-in were randomly assigned to a 6-week double-blind trial of either lithium (*n* = 14) or placebo (*n* = 11). Interestingly, 20 of 45 youths (45%) with severe mood dysregulation

were not randomly assigned to treatment because of significant clinical improvement during the placebo run-in. In the 6-week double-blind trial, there were no significant between-group differences on any clinical measures. The placebo group showed no improvement at all (a true negative trial), with no evidence that an increase in sample size would have changed the results.

In DSM-5, DMDD was included with the Depressive Disorders rather than with Bipolar and Related Disorders, in part because of studies showing that children with DMDD showed the onset of major depressive episodes rather than manic episodes later in life (Stringaris *et al.* 2010), raising the question of whether DMDD would respond to antidepressant treatment. A group of 49 children ages 7-17 years (mean age 11.4 years) were treated with methylphenidate and then randomly assigned in a double-blind fashion to either adjunctive citalopram or placebo for 8 weeks (Towbin *et al.* 2020). At the end of the trial, response was seen in a significantly higher proportion of participants assigned to the combination (35%) than in those assigned to stimulant with placebo (6%). Almost two-thirds of the citalopram groups did not respond, however, and the authors noted that there was no difference in measures of functional impairment.

Although risperidone has been shown to be effective in aggression (Aman *et al.* 2014; Blader *et al.* 2021), only one open trial of risperidone has been done in children with DMDD. Twenty-one ($n = 21$) participants with severe mood dysregulation were enrolled in an 8-week trial in which risperidone was titrated from 0.5 to 3 mg/day over the first 2 weeks (Krieger *et al.* 2011). By end of study at 8 weeks, there was a significant reduction in the Irritability subscale of the Aberrant Behavior Checklist (ABC).

Clinical Recommendations for Disruptive Behavior Disorders and Aggression

The Center for the Advancement of Children's Mental Health at Columbia University joined with the New York State Office of Mental Health to develop guidelines for treatment of aggression, which led to the Treatment Recommendations for the Use of Antipsychotics for Aggressive Youth (Pappadopulos *et al.* 2003; Schur *et al.* 2003). These recommendations call first for a thorough psychiatric evaluation of the child with severe aggression. Next, a psychosocial intervention should be used first when the aggression is the primary problem, such as in ODD, conduct disorder, or intermittent explosive disorder. The clinician should then treat any primary condition, such as ADHD, psychosis, or mood disorder, that may be causing or contributing to the aggression.

a_2 Agonists may be used for children with milder aggression or temper outbursts because the effect size of these medications on aggression is more modest (Hazell and Stuart 2003). An SSRI may be considered for patients with DMDD, particularly if prominent depressive symptoms are present (Towbin *et al.* 2020). If the aggression does not respond to these steps, then an atypical antipsychotic should be used. Different atypical antipsychotics should be tried as monotherapy before polypharmacy is tried (Pliszka 2009).

Tourette Syndrome

The prevalence of Tourette syndrome is estimated to be 0.7% in children (Comings *et al.* 1990). Tourette syndrome is characterized by multiple motor tics and by one or more vocal tics that occur frequently for longer than 1 year. More commonly, children have chronic motor or vocal tics, but treatment is the same as for Tourette syndrome.

Alpha-2 Adrenergic Receptor Agonists

Weisman *et al.* (2013) identified six placebo-controlled studies examining the effects of clonidine or guanfacine in patients with tics. A meta-analysis of these studies demonstrated a significant effect of a_2 agonists relative to placebo, with an SMD of 0.31 (95% CI, 0.15-0.48).

Antipsychotics

Weisman *et al.* (2013) reviewed five placebo-controlled studies of haloperidol, pimozide, ziprasidone, and risperidone. Two studies directly compared haloperidol and risperidone without a placebo control (Bruggeman *et al.* 2001; Gilbert *et al.* 2004), one study compared risperidone and clonidine (Gaffney *et al.* 2002), and one study compared haloperidol and the clonidine patch (Kang *et al.* 2009). In the meta-analysis, all antipsychotics were superior to placebo, with an SMD of 0.61 (95% CI, 0.36-0.86). There was no difference between the various antipsychotic agents with regard to their efficacy for reducing tics. Gaffney *et al.* (2002) found clonidine and risperidone to be equivalent in efficacy.

Murphy *et al.* (2005) reported on six cases of children and adolescents (age range = 8-19 years; mean age = 12.1 years) who had comorbid tic disorder and OCD and were treated with aripiprazole (mean dosage = 11.7 mg/day; range = 5-20 mg/day) for 12 weeks. The subjects experienced a mean reduction of 56% in the severity of their tics as assessed by the Yale Global Tic Severity Scale. Similarly, Yoo *et al.* (2006) treated 15 children and adolescents who had tic disorder with aripiprazole (mean dosage = 10.89 mg/day; range = 2.5-15 mg/day) and reported a mean reduction of 40% in Yale Global Tic Severity Scale scores; side effects were minimal. Two subjects experienced nausea, one experienced weight gain, and one experienced sedation. The sedation responded to dosage reduction.

In a case series, 11 consecutive patients with Tourette syndrome (mean age = 7 years; age range = 7-50 years) were treated with aripiprazole; the symptoms of the majority of these patients had been refractory to previous treatments with other antipsychotics (Davies *et al.* 2006). Ten of the 11 patients who were treated with aripiprazole improved, although to variable degrees. In the majority of patients, response was sustained with aripiprazole dosages ranging from 10 to 20 mg/day. Side effects were mild and transient. Zheng *et al.* (2016) reviewed six studies of the treatment of tics with aripiprazole. This study included two RCTs, but in these studies aripiprazole was compared only with tiapride, an antipsychotic not available in the United States. The other four studies were open trials. The review found aripiprazole to be well tolerated and effective in reducing tics relative to baseline levels.

Clinical Recommendations for Tourette Syndrome

The American Academy of Neurology has recently published guidelines for the treatment of Tourette syndrome (Pringsheim *et al.* 2019). The guidelines emphasized that if a tic is not severe or socially impairing, observation may be in order because tics typically wax and wane; in general, tics improve over time. The Comprehensive Intervention for Tics is a highly effective habit reversal treatment for tics; it should always be considered before medication is started (Woods *et al.* 2008). If conservative treatment fails, use of an a_2 agonist would be the first stage of medication treatment. Only if a agonists fail (and Comprehensive Intervention for Tics has not worked or is not available) should antipsychotics be considered. The American Academy of Neurology guidelines (Pringsheim *et al.* 2019) recommend individualizing the choice of first-or second-generation antipsychotics as the first choice, noting that the clinician should balance the risks and benefits of each class.

Although tics are known rare side effects of psychostimulants, it is of interest that in a double-blind, placebo-controlled study of methylphenidate, clonidine, and a combination of the two medications for children with comorbid ADHD and tic disorders, methylphenidate did not exacerbate tics. The best response of both the ADHD symptoms and the tics was found in the combined group (Tourette's Syndrome Study Group 2002). Atomoxetine was also found to reduce tics in patients with both ADHD and tic disorders (Allen *et al.* 2005). Thus, psychostimulants can be combined with a_2 agonists to control both ADHD and tics in patients with both disorders.

Schizophrenia

Cases of schizophrenia in children younger than age 13 years are very rare; however, the prevalence rises in adolescence, with peak onset between ages 15 and 30 years (McClellan and Werry 2001). The clinical features of the disorder are similar in youth and adults, and the same DSM-5 criteria are used to establish a diagnosis. Childhood-onset schizophrenia is associated with substantial impairment from positive and negative symptoms (Stentebjerg-Olesen *et al.* 2016).

Atypical Antipsychotics

Six atypical antipsychotics have FDA approval for the treatment of schizophrenia in adolescents: olanzapine (for ages [?] 13 years), risperidone ([?] 13 years), aripiprazole ([?] 13 years), quetiapine ([?] 13 years), paliperidone ER ([?] 12 years), and lurasidone ([?] 13 years). Ziprasidone, asenapine, and clozapine have been studied for treatment of schizophrenia in youths but do not have FDA approval. Information about dosages, monitoring, and adverse effects of atypical antipsychotics is provided in the appendix to this chapter.

Olanzapine

In a double-blind, placebo-controlled multicenter investigation of olanzapine (mean dosage = 11.1 mg/day) for the treatment of adolescents with schizophrenia (Kryzhanovskaya *et al.* 2009), 107 adolescents were randomly assigned to receive olanzapine (*n* = 72) or placebo (*n* = 35) for a 6-week trial. Olanzapine-treated adolescents had significantly greater improvements on the Brief Psychiatric Rating Scale for Children (BPRS-C) and in CGI-S scores compared with the placebo group. There was no significant difference in response rate (defined as a [?] 30% decrease in BPRS-C and a CGI-S score [?] 3) between the olanzapine (37.5%) and placebo (25.7%) groups. Significantly more olanzapine-treated adolescents had high aspartate aminotransferase/serum glutamic oxaloacetic transaminase. alanine aminotransferase/serum glutamic pyruvic transaminase, and prolactin levels, as well as low bilirubin levels and hematocrit values, during treatment. There was a significant increase in fasting triglycerides at endpoint in the olanzapine-treated adolescents. Early response at 2 and 3 weeks has been shown to predict ultimate response and remission at week 6 (Stentebjerg-Olesen *et al.* 2015).

Risperidone

Positive findings were reported in a double-blind, placebo-controlled multicenter trial of risperidone in the treatment of adolescents with schizophrenia (Haas *et al.* 2009b). One hundred sixty adolescents were randomly assigned to risperidone 1-3 mg/day (*n* = 55), risperidone 4-6 mg/day (*n* = 51), or placebo (*n* = 54) for a 6-week trial. Both dosage ranges of risperidone were significantly superior to placebo on the primary efficacy measure, the Positive and Negative Syndrome Scale (PANSS) total change score at endpoint. The most common adverse events in the risperidone 1-to 3-mg/day group were somnolence (24%), agitation (15%), and headache (13%). EPS (16%), dizziness (14%), and hypertonia (14%) were the most common adverse events in the risperidone 4-to 6-mg/day group. The investigators concluded that the overall risk-benefit ratio favored the lower dosage range of risperidone.

Aripiprazole

In a large double-blind, placebo-controlled multicenter trial of aripiprazole for the treatment of schizophrenia in adolescents (Findling *et al.* 2008), 302 adolescents were randomly assigned to receive aripiprazole 10 mg/day, aripiprazole 30 mg/day (after 5-or 11-day titration), or placebo over a 6-week period. Both dosages of aripiprazole led to statistically significant differences from placebo on the PANSS total score at week 6. The most common adverse events associated with aripiprazole were EPS, somnolence, and tremor. Early response to aripiprazole at weeks 2 and 3 has been shown to predict later response and remission (Correll *et al.* 2013).

Aripiprazole as maintenance treatment for adolescent schizophrenia was evaluated in a 52-week randomized, placebo-controlled withdrawal study (Correll *et al.* 2017). A total of 146 youths were randomly assigned to aripiprazole (n = 98) or placebo (n = 48) in the double-blind maintenance phase. Aripiprazole-treated youths had a significantly longer time to exacerbation of psychotic symptoms or impending relapse than placebo-treated youths (hazard ratio: 0.46).

Quetiapine

The efficacy of quetiapine in the treatment of schizophrenia in adolescents was evaluated in a 6-week double-blind, placebo-controlled trial in which subjects (N = 222) were randomly assigned to quetiapine 400 mg/day, quetiapine 800 mg/day, or placebo (Findling *et al.* 2012a). Both quetiapine dosages were significantly superior to placebo in reduction of total PANSS scores. The most common adverse events with quetiapine were somnolence, headache, and dizziness. Mean changes in body weight, total cholesterol, and total triglycerides were greater in the quetiapine groups than the placebo group.

Paliperidone Extended Release

Paliperidone ER was evaluated in a 6-week double-blind, placebo-controlled trial of 201 adolescents (ages 12-17 years) with schizophrenia (Singh *et al.* 2011). Paliperidone ER fixed dosing was weight based; youth weighing 29 kg to less than 51 kg received 1.5, 3, or 6 mg/day, whereas patients weighing at least 51 kg received 1.5, 6, or 12 mg/day. With weight-based treatment, only the medium dosage range (3-6 mg/day) led to significant improvement compared with placebo. The fixed dosages of 3, 6, and 12 mg/day were also superior to placebo. Somnolence, akathisia, insomnia, headache, and tremor were the most common adverse events in the paliperidone ER group.

The long-term safety of paliperidone ER was evaluated in a 2-year open-label study for 400 adolescents with schizophrenia (Savitz *et al.* 2015). The most frequently reported treatment-emergent adverse events were increased weight, headache, insomnia, nasopharyngitis, akathisia, schizophrenia exacerbation, and tremor. There were no clinically significant changes in weight or BMI. Hyperprolactinemia was found in 56% of patients, and 9.3% had prolactin-related adverse events. The most common EPS-related adverse events were parkinsonism (15.5%) and hyperkinesia (13.8%).

Ziprasidone

The efficacy of ziprasidone was evaluated in a 6-week double-blind, placebo-controlled trial for 283 adolescents ages 13-17 years with schizophrenia (Findling *et al.* 2013a). Ziprasidone was flexibly dosed (40-160 mg/day). There was no significant difference between ziprasidone and placebo on change from baseline to endpoint on the BPRS-Anchored. The most common adverse events in the ziprasidone group were somnolence and EPS. During the 26-week open-label follow-up, there were no clinically significant changes in metabolic indices and laboratory measures.

Asenapine

The efficacy of asenapine was assessed in an 8-week double-blind, placebo-controlled trial for adolescents ages 12-17 years with schizophrenia (Findling *et al.* 2015c). Asenapine dosing was 2.5 mg bid or 5 mg bid. Asenapine was not significantly superior to placebo on the primary efficacy measure of change from baseline to endpoint on the PANSS total score. Weight gain of 7% or greater, somnolence, sedation, and hypersomnia were more common in the asenapine group than the placebo group. Adverse events of akathisia, fasting glucose elevation, and EPS were more common in the asenapine 5 mg bid group than the placebo group. Youths who showed improvement during the acute phase maintained improvement in the 26-week open-label extension.

Lurasidone

Lurasidone was evaluated in a 6-week double-blind, placebo-controlled trial of 326 adolescents (ages 13-17 years) with schizophrenia (Goldman *et al.* 2017). Lurasidone dosage was fixed (40 or 80 mg/day). A significantly higher proportion of youths treated with lurasidone 40 mg/day and 80 mg/day than placebo-treated youths met responder criteria. The most common adverse events with lurasidone were nausea, somnolence, akathisia, vomiting, and sedation.

Youths who continued open-label lurasidone treatment showed continued improvement over a 2-year period (Correll *et al.* 2022). There were minimal effects on body weight, lipids, glycemic indices, and prolactin.

Clozapine

A 6-week double-blind, placebo-controlled comparison of clozapine and haloperidol was conducted in 21 children and adolescents (ages 6-18 years) with schizophrenia (Kumra *et al.* 1996). Clozapine (mean dosage = 176 mg/day; range = 25-525 mg/day) was significantly superior to haloperidol (mean dosage = 16 mg/day; range = 7-27 mg/day) in reducing positive and negative symptoms of schizophrenia. Clozapine improved interpersonal functioning and enabled patients to live in a less restrictive setting. However, side effects were significant with clozapine. One patient had a seizure, and three patients were given anticonvulsants after they became more irritable and aggressive and experienced epileptiform changes on electroencephalogram. Mild to moderate neutropenia, weight gain, and sinus tachycardia were the other major side effects.

Comparison of Atypical Antipsychotics

In a 12-week open-label trial, risperidone (mean dosage = 1.6 mg/day) was compared with olanzapine (mean dosage = 8.2 mg/day) in the treatment of 25 children with schizophrenia (Mozes *et al.* 2006). Both treatment groups showed similar, significant improvement as measured by PANSS total and subscale scores.

In an 8-week double-blind study, 50 children and adolescents (ages 8-19 years) with psychotic disorders were randomly assigned to receive risperidone (mean dosage = 4 mg/day), olanzapine (mean dosage = 12.3 mg/day), or haloperidol (mean dosage = 5 mg/day) (Sikich *et al.* 2004). Eighty-eight percent of patients treated with olanzapine, 74% treated with risperidone, and 53% treated with haloperidol met response criteria (CGI-I scores of much or very much improved and at least a 20% reduction in BPRS-C total score).

Clozapine was compared with olanzapine in an 8-week double-blind randomized trial (Shaw *et al.* 2006). Twenty-five youths (ages 7-16 years) with schizophrenia that was resistant to treatment with at least two antipsychotics participated in the trial. Clozapine (mean dosage = 327 mg/day) led to significant improvement on all outcome measures, whereas olanzapine (mean dosage = 19.1 mg/day) led to improvement on some outcome measures. Improvement in negative symptoms was significantly greater for the clozapine group.

In an 8-week double-blind trial comparing olanzapine and risperidone against the typical antipsychotic molindone in 116 children and adolescents with early-onset schizophrenia or schizoaffective disorder (Sikich *et al.* 2008), no significant differences were observed in rates of response (CGI-I score [?] 2 and [?] 20% reduction in PANSS total score) among the treatment groups (risperidone 46%, olanzapine 34%, and molindone 50%). Significantly greater weight gain occurred with olanzapine and risperidone than with molindone.

A double-blind maintenance study followed this acute controlled trial of children and adolescents with early-onset schizophrenia or schizoaffective disorder (Findling *et al.* 2010). Of the 54 youths eligible for the maintenance phase, 14 (26%) completed 44 weeks of treatment. No significant differences were found between olanzapine, risperidone, and molindone in reduction of symptoms or time to discontinuation.

In an 8-week double-blind trial comparing paliperidone ER and aripiprazole in 228 adolescents with schizophrenia (Savitz *et al.* 2015), there was no significant difference between the paliperidone ER group and the aripiprazole group on change in PANSS scores from baseline to endpoint. Both medication groups showed improvement in symptoms and functional outcomes.

The efficacy of quetiapine extended release versus aripiprazole was compared in 231 youths (ages 12-17 years) with schizophrenia spectrum and other psychotic disorders in a 12-week multicenter trial (Pagsberg *et al.* 2017a). There were no significant differences in outcome ratings (change in PANSS positive score from baseline to endpoint) between the quetiapine and the aripiprazole groups.

Typical Antipsychotics

Haloperidol

Haloperidol has been compared with placebo and other typical antipsychotics in controlled trials in youths. In a 10-week double-blind, placebo-controlled crossover study, the safety and efficacy of haloperidol were assessed in 12 hospitalized children (ages 5-12 years) with schizophrenia. Haloperidol (optimal dosage range = 0.5-3.5 mg/day) was significantly superior to placebo in improving overall clinical functioning and reducing ideas of reference, delusions, and hallucinations. Common side effects were acute dystonic reaction, drowsiness, and dizziness (Spencer *et al.* 1992).

Haloperidol and loxapine were compared in a 4-week double-blind, placebo-controlled study of 75 adolescent inpatients with schizophrenia. Both haloperidol and loxapine were significantly superior to placebo, and there was no significant difference in efficacy between the two medications. Response rates (based on CGI-I scores) were 87.5% for loxapine, 70% for haloperidol, and 36.4% for placebo. Common side effects were sedation, EPS, and somnolence (Pool *et al.* 1976).

Thiothixene

Thiothixene was compared with thioridazine in a 6-week single-blind study of 21 adolescent inpatients with schizophrenia. Thiothixene (optimal mean dosage = 16.2 mg/day) and thioridazine (optimal mean dosage = 178 mg/day) were equally effective in controlling symptoms, although most of the adolescents continued to be quite impaired. Thiothixene was less sedating than thioridazine (Realmuto *et al.* 1984). Thiothixene was also compared with trifluoperazine in an 8-week double-blind study of 16 children (ages 8-15 years) with schizophrenia (Wolpert *et al.* 1967). The effects of both medications were similar in terms of decreasing avoidance behavior, reducing stereotypic behavior, and increasing peer socialization.

Meta-Analyses: Pharmacological Treatments

A systematic review and network meta-analysis of antipsychotics (aripiprazole, asenapine, paliperidone, risperidone, quetiapine, olanzapine, and ziprasidone) for treatment of schizophrenia spectrum disorders in children and adolescents showed comparable efficacy among antipsychotics for early-onset schizophrenia, except that efficacy appeared inferior for ziprasidone and unclear for asenapine (Pagsberg *et al.* 2017b).

A network meta-analysis of antipsychotics for treatment of children and adolescents showed clozapine was significantly more effective than other antipsychotics, but ziprasidone showed no efficacy (Krause *et al.* 2018).

Clinical Recommendations for Schizophrenia

Both typical and atypical antipsychotics have demonstrated effectiveness in the treatment of schizophrenia in youths, although the sample sizes have been small in the trials of typical antipsychotics. Because fewer EPS and instances of tardive dyskinesia have been reported with atypical antipsychotics, it would be reasonable to initiate treatment with an atypical antipsychotic for a child with schizophrenia. It is important to monitor weight and metabolic parameters for children who receive atypical antipsychotics. Clozapine should be considered for treatment-resistant schizophrenia (McClellan *et al.* 2013).

Antipsychotics should be administered at adequate dosages for a period of 6 weeks to assess efficacy. If there is no response or if intolerable side effects occur, a trial of a different antipsychotic should be initiated (American Academy of Child and Adolescent Psychiatry 2012).

There are limited data to guide maintenance treatment. Because the majority of youths will have a second psychotic episode within 5-7 years of stabilization, there is a significant risk of relapse with medication withdrawal (Kumra 2000). Maintenance treatment should be provided to most youths with schizophrenia to improve functioning and prevent relapse (American Academy of Child and Adolescent Psychiatry 2012). The aim is to use the lowest effective dosage of medication to reduce the risk of adverse events. For youths with prolonged remission, it may be possible to discontinue medication, but long-term monitoring will be necessary because of possible reemergence of psychotic symptoms.

Autism Spectrum Disorder

Autism spectrum disorder (ASD) is a new DSM-5 disorder that encompasses the previous DSM-IV categories of autistic disorder (autism), Asperger's disorder, and pervasive developmental disorder not otherwise specified. Symptoms of ASD represent a continuum of mild to severe impairments in two core domains: deficits in social communication and social interaction and restricted, repetitive patterns of behavior, interests, and activities (American Psychiatric Association 2013). Associated behavioral features include hyperactivity, stereotypies, attentional problems, self-injurious behavior, aggression, mood lability, anxiety, obsessions, and compulsions. ASD is estimated to have a prevalence of up to 18.5 per 1,000 population (Maenner *et al.* 2020). The majority of children with the disorder will continue to have significant social and communication impairments throughout adulthood (Bieleninik *et al.* 2017).

Atypical Antipsychotics

For the treatment of irritability associated with ASD, the FDA has approved risperidone (for patients age [?] 5 years) and aripiprazole (age [?] 6 years). Lurasidone, olanzapine, quetiapine, and ziprasidone have been studied for ASD but do not have FDA approval for use by youths. Information about dosages, monitoring, and adverse effects of atypical antipsychotics is provided in the appendix to this chapter.

Risperidone

One hundred one children (ages 5-17 years) with DSM-IV-defined autistic disorder participated in an 8-week double-blind, placebo-controlled trial of risperidone (dosage range = 0.5-3.5 mg/day; mean dosage= 1.8 mg/day) (McCracken *et al.* 2002). A significantly greater positive response (defined as a 25% decrease on the Irritability subscale of the ABC and a rating of much or very much improved on the CGI-I) was found for the risperidone group (69%) than the placebo group (12%). Adverse events of increased appetite, fatigue, drowsiness, dizziness, and drooling were more common in the risperidone group than in the placebo group. Mean weight gain was 2.7 kg in the risperidone group and 0.8 kg in the placebo group. An 18-month follow-up showed that the majority of subjects who responded to risperidone during intermediate-length treatment continued to show improvement (McDougle *et al.* 2005).

In a 24-month follow-up of 84 of these youths, there was continued improvement in maladaptive behavior from baseline (Aman *et al.* 2015). Social skills improved and irritability decreased for youths who were taking risperidone at follow-up. Risperidone treatment was associated with enuresis, excessive appetite, and weight gain.

In an 8-week double-blind, placebo-controlled trial, 79 children (ages 5-12 years) with a DSM-IV diagnosis of autistic or other pervasive developmental disorder were randomly assigned to receive either placebo or risperidone (mean dosage = 1.5 mg/day). Risperidone-treated patients exhibited a 64% improvement over baseline irritability, compared with a 30.7% improvement in subjects receiving placebo (Shea *et al.* 2004).

In a 6-month placebo-controlled study of 40 children (ages 2-9 years) with autism, risperidone (1 mg/day) decreased aggressiveness, hyperactivity, and irritability and improved social responsiveness and nonverbal communication. Appetite increase, weight gain, sedation, and transient dyskinesias were reported in the risperidone-treated children (Nagaraj *et al.* 2006).

The long-term effects of risperidone were assessed in youths (ages 5-17 years) with ASD (Troost *et al.* 2005). Twenty-four youths received risperidone for 6 months, followed by a double-blind discontinuation to placebo or continued risperidone. Risperidone was superior to placebo in preventing relapse, with relapse rates of 25% and 75%, respectively.

In a double-blind, placebo-controlled risperidone dosing study in 96 youths (ages 5-17 years), high-dosage risperidone (1.25 mg/day for youths weighing 20 to < 45 kg; 1.75 mg/day for youths weighing [?] 45 kg) was significantly superior to placebo in baseline-to-endpoint change in score on the ABC Irritability subscale (Kent *et al.* 2013b). However, there was no significant difference between scores of patients given low-dosage risperidone (0.125 mg/day for youths weighing 20 to < 45 kg; 0.175 mg/day for youths weighing [?] 45 kg) and scores of patients given placebo. In an open-label extension study with flexibly dosed risperidone, all groups showed additional improvement in efficacy scores (Kent *et al.* 2013a).

The comparative efficacy of risperidone and haloperidol was assessed in an 8-week double-blind trial that included 30 children and adolescents with DSM-IV autistic disorder (Miral *et al.* 2008). Risperidone produced significantly greater reductions in scores on the ABC as well as on other scales used to assess symptoms of autism. An open-label continuation study (Gencer *et al.* 2008) of this controlled trial showed that risperidone-treated patients had greater improvement than haloperidol-treated patients on CGI ratings and on the ABC.

In a 24-week randomized trial, combined treatment with risperidone and PT was compared with risperidone alone for the treatment of severe behavioral problems in 124 children with ASD (Scahill *et al.* 2012). Combined treatment was superior to medication alone in reduction of noncompliant behavior as assessed by the Home Situation Questionnaire. In a 1-year follow-up, there was no significant difference between treatment groups on noncompliant behavior (Arnold *et al.* 2012).

Aripiprazole

The efficacy of aripiprazole in the treatment of irritability was evaluated in 218 children and adolescents with DSM-IV autistic disorder in an 8-week double-blind, placebo-controlled

trial (Marcus *et al.* 2009). Aripiprazole dosages were 5, 10, or 15 mg/day. Compared with placebo, all aripiprazole dosages produced significantly greater improvement in mean scores on the ABC Irritability subscale. The most common adverse events were sedation, tremor, and somnolence. The efficacy of aripiprazole was assessed in another 8-week double-blind, placebo-controlled trial that included 98 children and adolescents with DSM-IV autistic disorder (Owen *et al.* 2009). Aripiprazole dosages were 5, 10, or 15 mg/day. Significantly greater improvements in mean scores on the ABC Irritability subscale were seen with aripiprazole versus placebo. Rates of EPS-related adverse events were 14.9% with aripiprazole and 8% with placebo.

Aripiprazole was also shown to be significantly superior to placebo on the ABC (Japanese version) Irritability subscale score in an 8-week double-blind, placebo-controlled study of 92 children and adolescents (ages 6-17 years) with ASD in Japan (Ichikawa *et al.* 2017).

Long-term maintenance treatment with aripiprazole was examined in a double-blind, placebo-controlled relapse prevention trial for 86 youths with ASD (Findling *et al.* 2014). There was no statistically significant difference in time to relapse between aripiprazole and placebo. Relapse rates at week 16 were 35% for the aripiprazole group and 52% for the placebo group.

The efficacy of aripiprazole versus risperidone was compared in a 2-month randomized, double-blind trial that included 59 children and adolescents with ASD (Ghanizadeh *et al.* 2014). Both aripiprazole and risperidone groups had lower scores on the ABC at endpoint than at baseline; there was no statistically significant difference between these medications.

In a 10-week double-blind parallel-group study, 80 children and adolescents (ages 6-17 years) with ASD were randomly assigned to aripiprazole or risperidone. All participants significantly improved on the ABC Irritability subscale after 1 week and continued to improve for the remaining 9 weeks (DeVane *et al.* 2019).

Lurasidone

The efficacy of lurasidone for the treatment of irritability was evaluated for 150 children and adolescents (ages 6-17 years) in a 6-week double-blind placebo-controlled trial (Loebel *et al.* 2016). Lurasidone dosages were 20 mg/day or 60 mg/day. Neither fixed dosage of lurasidone showed a statistically significant difference from placebo on the ABC Irritability subscale. The most common adverse events with lurasidone were vomiting and somnolence.

Olanzapine

The efficacy of olanzapine was evaluated in an 8-week double-blind, placebo-controlled trial that included 11 children and adolescents with pervasive developmental disorders (Hollander *et al.* 2006). Rates of response (CGI-I score [?] 2) were 50% for olanzapine-treated patients and 20% for placebo-treated patients. Olanzapine-treated patients experienced significantly greater weight gain (mean 7.5 lb for olanzapine vs. 1.5 lb for placebo-treated patients).

In a 12-week open-label study of olanzapine (mean dosage = 7.8 mg/day) in eight patients (ages 5-42 years) with DSM-IV autistic disorder or pervasive developmental disorder not otherwise specified, the six patients who completed the trial showed

much or very much global improvement (Potenza *et al.* 1999). Significant improvements were found in hyperactivity, social relatedness, affectual responses, sensory responses, language usage, self-injurious behavior, aggression, irritability, anxiety, and depression. The most significant adverse effects were increased appetite and weight gain in six patients and sedation in three patients.

In a 3-month open study of olanzapine (dosage range = 1.25-20 mg/day) in 25 subjects (ages 6-16 years) with pervasive developmental disorder, significant global improvement was reported. The most common side effect was weight gain (mean = 4.8 kg) (Kemner *et al.* 2002).

Olanzapine was compared with haloperidol in a 6-week open trial of 12 children (ages 4-11 years) with DSM-IV autistic disorder (Malone *et al.* 2001). Both the olanzapine treatment (mean dosage = 7.9 mg/day) and the haloperidol treatment (mean dosage = 1.4 mg/day) reduced symptoms of social withdrawal and stereotypies and improved speech and object relations.

Quetiapine

The effectiveness of quetiapine (dosage range = 100-350 mg/day) was evaluated in a 16-week open-label trial of six pediatric patients with DSM-

IV autistic disorder (Martin *et al.* 1999). No significant behavioral improvements were found from baseline to endpoint.

In a 12-week open-label study of quetiapine in nine adolescents (mean age = 14.6 years) with DSM-IV autistic disorder, only two patients were much or very much improved at study endpoint (Findling *et al.* 2004).

Ziprasidone

The efficacy of ziprasidone was evaluated in a 6-week open-label study of 12 adolescents with autism (Malone *et al.* 2007). Ziprasidone dosages ranged from 20 mg/day to 160 mg/day (mean dosage = 98.3 mg/day). Of the 12 patients, 9 (75%) were considered treatment responders (based on CGI-I scores [?] 2). The mean change in QTc interval from baseline to endpoint was 14.7, which was a statistically significant increase. There was no significant weight change.

The efficacy and safety of ziprasidone in children, adolescents, and young adults with autism were evaluated in an open-label study in which 12 pediatric patients (ages 8-20 years) were treated with ziprasidone (mean daily dosage = 59.23 mg) for at least 6 weeks (McDougle *et al.* 2002). Fifty percent of patients were responders based on a CGI rating of much improved or very much improved. Transient sedation was the most common side effect.

Typical Antipsychotics

Haloperidol

Haloperidol has been the most widely studied typical antipsychotic for the treatment of autism in children and adolescents. In double-blind, placebo-controlled studies, haloperidol has been shown to be significantly superior to placebo in reducing maladaptive behaviors and facilitating learning on discrimination tasks (Campbell *et al.* 1982); increasing retention of discrimination learning and decreasing maladaptive behaviors in the classroom (Anderson *et al.* 1984); decreasing occurrence of stereotypies and increasing orienting reactions of children (Cohen *et al.* 1980); and decreasing hyperactivity, temper tantrums, withdrawal, and stereotypies and increasing relatedness (Anderson *et al.* 1989). Optimal dosages of haloperidol in these studies ranged from 0.25 to 4 mg/day. The most common side effects were sedation, increased irritability, and acute dystonic reactions. Weight gain was modest (0.2 kg) in autistic children who received haloperidol 0.25-3.5 mg/day for a 6-month period (Silva *et al.* 1993).

The long-term efficacy of haloperidol was assessed in 48 children (ages 2-8 years) with autism who received haloperidol for 6 months (Perry *et al.* 1989). Haloperidol remained effective throughout the 6-month treatment period, and it was equally effective whether it was given continuously or on a discontinuous schedule consisting of 5 days on haloperidol and 2 days on placebo. Children who had symptoms of irritability, angry and labile affect, and uncooperativeness were the best responders to haloperidol.

Serotonin Reuptake Inhibitors

Information about dosages, monitoring, and adverse effects of serotonin reuptake inhibitors is provided in the appendix to this chapter.

Fluoxetine

Controlled trials of fluoxetine for treatment of repetitive behaviors have yielded mixed results.

The efficacy of liquid fluoxetine in treating repetitive behaviors in autism was assessed in 45 children and adolescents with ASD. Subjects were randomly assigned to two 8-week acute phases in a double-blind crossover study (Hollander *et al.* 2005). Low-dosage liquid fluoxetine (mean dosage = 9.9 mg/day) was superior to placebo in reducing repetitive behaviors.

The efficacy of fluoxetine in treating obsessive-compulsive symptoms in 146 children and adolescents (ages 7.5-18 years) with ASD was assessed in a 16-week randomized double-blind, placebo-controlled trial (Reddihough *et al.* 2019). The fluoxetine-treated group had significantly lower scores for obsessive compulsive behaviors at 6 weeks than the placebo group.

In a 14-week RCT, fluoxetine was not shown to be superior to placebo for the treatment of repetitive behaviors in 158 youths (ages 5-17 years) with ASD (Herscu *et al.* 2020).

Fluvoxamine

A double-blind, placebo-controlled study investigating fluvoxamine treatment (mean dosage = 106.9 mg/day) in 34 children and adolescents with DSM-IV autistic disorder did not find significant clinical improvement with fluvoxamine (McDougle *et al.* 2000).

Sertraline

The efficacy of sertraline to improve expressive language development was evaluated in a 6-month double-blind placebo-controlled trial of 58 children (ages 24-72 months) (Potter *et al.* 2019). There was no significant difference between sertraline and placebo on change in expressive language scores from baseline to endpoint.

Citalopram

The efficacy of citalopram was evaluated for treatment of repetitive behavior in children with ASD (King *et al.* 2009). One hundred forty-nine children and adolescents with ASD were randomly assigned to receive citalopram or placebo in a 12-week controlled trial. The mean dosage of citalopram at endpoint was 16.5 mg/day. There was no significant difference in rates of response (CGI-I score [?] 2) between citalopram-treated patients (39.2%) and placebo-treated patients (34.2%). No difference was found in reduction in CY-BOCS scores between the citalopram group and the placebo group. Adverse events that were significantly more common in the citalopram group were increased energy level, impulsiveness, hyperactivity, stereotypy, decreased concentration, diarrhea, insomnia, and dry skin or pruritus.

Escitalopram

In a 10-week open-label study, 28 children and adolescents (ages 6-17 years) with pervasive developmental disorder received escitalopram. There was significant improvement in irritability and clinical global functioning. Twenty-five percent of youths responded at escitalopram daily dosages less than 10 mg, and 36% of youths responded at dosages greater than or equal to 10 mg (Owley *et al.* 2005).

Clomipramine

Controlled trials with clomipramine in the treatment of ASD have yielded mixed results. Clomipramine and haloperidol were compared in a placebo-controlled crossover study for 7 weeks with active treatment (Remington *et al.* 2001). Thirty-six patients (ages 10-36 years) with DSM-IV autistic disorder were randomly assigned to clomipramine (mean dosage = 128.4 mg/day; range = 100-150 mg/day), haloperidol (mean dosage = 1.3 mg/day; range = 1-1.5 mg/day), or placebo. A significant advantage for haloperidol was found on global measures of autism symptom severity and on specific measures of irritability and hyperactivity. Clomipramine was comparable to haloperidol only among patients who were able to complete a full therapeutic trial. However, significantly fewer patients receiving clomipramine versus haloperidol were able to complete the trial (37.5% vs. 69.7%, respectively) for reasons related to inefficacy, side effects, or behavioral problems.

Other Antidepressants

Mirtazapine

In an open-label study of mirtazapine (dosage range = 7.5-45 mg/day; mean = 30.3 mg/day) in 26 patients (ages 3-23 years) with pervasive developmental disorders, 9 patients (34.6%) were judged much or very much improved in symptoms of aggression, self-injury, irritability, hyperactivity, anxiety, depression, and insomnia (Posey *et al.* 2001). Mirtazapine did not improve symptoms of social or communication impairment. Common side effects included irritability, increased appetite, and transient sedation.

Venlafaxine

The effectiveness of venlafaxine was assessed in an open retrospective study of 10 patients (ages 3-21 years) with pervasive developmental disorders (Hollander *et al.* 2000). Six of the 10 patients who received venlafaxine (mean dosage = 24.4 mg/day; range = 6.25-50 mg/day) over an average of 5 months were much or very much improved. Improvements were observed in repetitive behaviors, restricted interests, social deficits, communication and language function, inattention, and hyperactivity. Side effects of venlafaxine included behavioral activation, nausea, inattention, and polyuria.

Reboxetine

Eleven adolescents with ASD with depressive and ADHD symptoms were treated with reboxetine (maximum dosage 4 mg/day) in a 12-week open-label trial (Golubchik *et al.* 2013). Significant but modest decreases in depressive and ADHD symptoms were found with reboxetine treatment. Irritability and insomnia were the most commonly reported adverse events.

Mood Stabilizers

Information about dosages, monitoring, and adverse effects of mood stabilizers is provided in the appendix to this chapter.

Lamotrigine

Twenty-eight children (ages 3-11 years) with DSM-IV autistic disorder participated in a double-blind, placebo-controlled study of lamotrigine (mean maintenance dosage = 5 mg/kg/day) for a 12-week study period (Belsito *et al.* 2001). There were no significant differences between the lamotrigine and placebo groups on severity of behavioral symptoms at endpoint. Insomnia and hyperactivity were the most frequently reported side effects. No children in the study were withdrawn because of rash.

Valproate

Three double-blind, placebo-controlled trials have been conducted to assess the efficacy of valproate in the treatment of ASD. In one 8-week trial in 13 children, divalproex was superior to placebo in improvement of repetitive behaviors (Hollander *et al.* 2006). In another 8-week trial that included 27 youths with ASD, divalproex significantly reduced symptoms of irritability compared with placebo (Hollander *et al.* 2010). However, valproate was not superior to placebo in reduction of aggression and irritability for 30 youths with pervasive developmental disorders who participated in an 8-week trial (Hellings *et al.* 2005).

Oxcarbazepine

In a retrospective case series of 30 youths (ages 5-21 years) with ASD, 14 patients (47%) who were treated with oxcarbazepine (mean final dosage = 1,360 mg/day) attained CGI-I scores of 2 or lower on ratings of irritability and agitation symptoms (Douglas *et al.* 2013).

Levetiracetam

A 10-week double-blind, placebo-controlled trial was conducted to assess the efficacy of levetiracetam in the treatment of 20 children with autism (Wasserman *et al.* 2006). The mean maximum dosage of levetiracetam was 862.5 mg/day. There were no significant

differences between levetiracetam and placebo on measures of global improvement of autism, aggression and affective instability, and impulsivity and hyperactivity.

Other Agents

Lithium

In a retrospective chart review of 30 children with ASD who were treated with lithium (mean blood level 0.70 mEq/L), 13 youths (43%) were rated as improved on the CGI-I (Siegel *et al.* 2014). Vomiting, tremor, fatigue, irritability, and enuresis were the most common adverse effects.

Clonidine

A double-blind, placebo-controlled crossover study of transdermal clonidine (0.005 mg/kg/day or placebo delivered via a weekly transdermal patch) in nine patients (ages 5-33 years) with DSM-III-R autistic disorder was conducted for a total active period of 8 weeks (Fankhauser *et al.* 1992). Significantly greater improvement with clonidine, compared with placebo, was found on measures of social relationship, affectual responses, and sensory responses. In a double-blind, placebo-controlled crossover trial of clonidine in eight children with autistic disorder, clonidine was found to be modestly effective in reducing irritability and hyperactivity (Jaselskis *et al.* 1992).

Guanfacine Extended Release

The efficacy of guanfacine ER was assessed in an 8-week randomized, placebo-controlled trial in 62 children with ASD (Scahill *et al.* 2015). The group randomly assigned to guanfacine ER (modal dosage at week 8: 3 mg/day) showed significantly greater decline (43.6%) in scores on the ABC Hyperactivity subscale compared with the placebo group (13.2%). The most common adverse events were drowsiness, fatigue, and decreased appetite.

In a later report involving the same cohort of patients with ASD, guanfacine ER was noted to be superior to placebo in reducing oppositional and repetitive behaviors (Politte *et al.* 2018) at the end of the 8-week trial.

Methylphenidate

A meta-analysis of four methylphenidate trials for treatment of ADHD symptoms in children with pervasive developmental disorders showed an effect size of 0.67 (Reichow *et al.* 2013). The most common adverse events were decreased appetite, insomnia, depressive symptoms, irritability, and social withdrawal.

An extended-release methylphenidate formulation has also been shown to reduce hyperactive and impulsive behavior in children with ASD and

ADHD symptoms (Pearson *et al.* 2013). In 24 children with ASD and symptoms of inattention and hyperactivity, extended-release methylphenidate at low, medium, and high dosages was shown to produce greater improvement than placebo in cognitive task performance (Pearson *et al.* 2020).

Atomoxetine

Atomoxetine as a treatment for symptoms of ADHD in children and adolescents with ASD was examined in a double-blind, placebo-controlled 8-week trial that included 97 youths (Harfterkamp *et al.* 2012). The atomoxetine dosage was 1.2 mg/kg/day. There

was a statistically significant difference between atomoxetine and placebo on change from baseline to endpoint ADHD Rating Scale-IV scores. Adverse effects of nausea, decrease in appetite, fatigue, and early morning awakening were more common in the atomoxetine group than in the placebo group. In a subsequent analysis, atomoxetine did not improve social functioning, but there was some improvement in stereotyped behaviors, inappropriate speech, and fear of change (Harfterkamp *et al.* 2014).

In a placebo-controlled crossover trial that included 16 youths with ASD and ADHD symptoms, atomoxetine was superior to placebo in reduction of hyperactivity and impulsivity symptoms as measured on the ABC (Arnold *et al.* 2006).

Long-term efficacy and tolerability of atomoxetine were assessed in a 20-week follow-up of an 8-week controlled trial in 88 youths with ASD and ADHD symptoms (Harfterkamp *et al.* 2013). Continued treatment with atomoxetine resulted in further improvement of ADHD symptoms. Adverse events, particularly nausea and fatigue, diminished over time with continued treatment.

Atomoxetine, PT, and their combination were assessed in a 10-week randomized placebo-controlled trial in 128 children (ages 5-14 years) with ASD and ADHD symptoms. Atomoxetine--both alone and with PT--

resulted in significant improvement in ADHD symptoms (Handen *et al.* 2015), and no effects on sleep quality were found (Hollway *et al.* 2018). A 24-week extension study showed that atomoxetine responders maintained their response (Smith *et al.* 2016), and a majority maintained improvement at 1.5-year follow-up (Arnold *et al.* 2018).

Bumetanide

The efficacy of bumetanide for the treatment of 60 children with ASD was evaluated in a 3-month double-blind, placebo-controlled trial (Lemonnier *et al.* 2012). The bumetanide dosage was 1 mg/day. Bumetanide was significantly superior to placebo in reduction of symptoms on the primary outcome measure, the Childhood Autism Rating Scale. Occasional mild hypokalemia was the most common adverse event.

Intranasal Oxytocin

Intranasal oxytocin has been examined as a treatment for ASD in controlled trials, with mixed results. Oxytocin nasal spray (18 or 24 IU) or placebo was administered to 16 youths with ASD in a double-blind, placebo-controlled crossover design (Guastella *et al.* 2010). Compared with placebo, oxytocin significantly improved emotion recognition.

In a double-blind, placebo-controlled trial, 36 male youths with ASD received 24 or 12 IU of oxytocin or placebo over a 4-day period (Dadds *et al.* 2014). There were no significant differences between intranasal oxytocin and placebo on measures of social interaction skills, repetitive behaviors, or emotion recognition.

Intranasal oxytocin has been evaluated for the treatment of social deficits in a double-blind, placebo-controlled trial in 50 adolescents with ASD (Guastella *et al.* 2015). There was no significant difference between oxytocin and placebo on the outcome of social responsiveness.

Arbaclofen

The efficacy of arbaclofen was assessed in a 12-week double-blind, placebo-controlled trial that included 150 children, adolescents, and young adults (Delahunty *et al.* 2013).

Arbaclofen was titrated to a maximum of 10 mg three times daily for youths ages 5-11 years and 15 mg three times daily for youths ages 12-21 years. There was no significant difference between arbaclofen and placebo in reducing lethargy or social withdrawal.

Omega-3 Fatty Acids

Omega-3 fatty acids have been evaluated in double-blind, placebo-controlled trials for the treatment of hyperactivity for children with ASD and have shown mixed results. No statistically significant difference between omega-3 fatty acids and placebo has been found on hyperactivity measures in some studies (Bent *et al.* 2011, 2014), although one study reported an advantage of omega-3 fatty acids compared with placebo for hyperactivity and stereotypies (Amminger *et al.* 2007). In a double-blind, placebo-controlled trial, omega-3 plus vitamin D was shown to reduce irritability in children with ASD (Mazahery *et al.* 2019).

Folinic Acid

Folinic acid (2 mg/kg/day) was evaluated as a treatment for language impairment in 48 children (mean age 7 years) with ASD in a 12-week double-blind, placebo-controlled trial (Frye *et al.* 2018). Improvement in verbal communication was significantly greater in the folinic acid group than in the placebo group.

Memantine

Memantine as an adjunctive treatment to risperidone for ASD was assessed in a 10-week double-blind, placebo-controlled trial in 40 children (Ghaleiha *et al.* 2013a). The memantine dosage was titrated to 20 mg/day, and the risperidone dosage to 3 mg/day. Compared with the placebo group, the group that received adjunctive memantine had a significantly greater reduction in the Irritability score on the ABC-Community version. There was no significant difference in adverse effects between the groups.

Amantadine

Amantadine as adjunctive treatment to risperidone for treatment of 40 children with ASD was evaluated in a 10-week double-blind, placebo-controlled trial (Mohammadi *et al.* 2013). Amantadine was titrated to 100-150 mg/day, and risperidone was titrated to 1-2 mg/day. Compared with the placebo group, the adjunctive amantadine group had a significantly greater reduction in Hyperactivity and Irritability scores on the ABC-Community version. There were no significant adverse effects.

Riluzole

The efficacy of riluzole as adjunctive treatment to risperidone was assessed in a 10-week double-blind, placebo-controlled trial for 40 children with ASD (Ghaleiha *et al.* 2013b). Riluzole was titrated to 50-100 mg/day, and risperidone was titrated to 2-3 mg/day. Significantly greater improvement in irritability, as assessed by the ABC-Community version, was found for the adjunctive riluzole group compared with the placebo group. Increased appetite and weight gain were more common in the riluzole group than the placebo group.

Buspirone

Buspirone as adjunctive treatment to risperidone was evaluated in an 8-week double-blind, placebo-controlled trial for 40 youths with autism (Ghanizadeh and Ayoobzadehshirazi 2015). The mean dosage of buspirone was 6.7 mg/day. Compared with the placebo group, the adjunctive buspirone group showed a significantly greater reduction in scores on the Irritability subscale of the ABC-Community version. The most common adverse events in the buspirone group were increased appetite, drowsiness, and fatigue.

In a 24-week RCT in children ages 2-6 years with ASD, low-dosage buspirone (2.5 mg bid) produced significantly greater improvement in restricted and repetitive behaviors compared with placebo (Chugani *et al.* 2016).

Celecoxib

Adjunctive treatment with celecoxib and risperidone was evaluated in a 10-week double-blind, placebo-controlled trial that included 40 children with autism (Asadabadi *et al.* 2013). Celecoxib was titrated to 300 mg/day and risperidone to 3 mg/day. Adjunctive celecoxib was superior to placebo in reducing irritability, social withdrawal, and stereotypy as measured on the ABC-Community version.

Pentoxifylline

The efficacy of adjunctive pentoxifylline with risperidone was assessed in a 10-week double-blind, placebo-controlled trial that included 40 children with a DSM-IV-TR (American Psychiatric Association 2000) diagnosis of autistic disorder (Akhondzadeh *et al.* 2010). Pentoxifylline was titrated to 600 mg/day, and risperidone was titrated to 3 mg/day. Adjunctive pentoxifylline was superior to placebo in reducing scores on the ABC-Community version subscales for irritability, lethargy and social withdrawal, stereotypic behavior, hyperactivity and noncompliance, and inappropriate speech. There was no significant difference between the groups in adverse events.

N-Acetylcysteine

A meta-analysis of five RCTs of NAC with sample sizes ranging from 29 to 98 children with ASD showed that after 8-12 weeks, NAC supplementation improved symptoms of hyperactivity and irritability on the ABC total score (Lee *et al.* 2021). The most common adverse events with NAC supplementation were gastrointestinal symptoms (vomiting, constipation), increased appetite, and upper respiratory infection.

Meta-Analyses: Pharmacological Treatment

With regard to irritability as a feature of ASD, there has been a systematic review and network meta-analysis of the effects of atypical antipsychotics including risperidone, aripiprazole, and lurasidone (Fallah *et al.* 2019). Eight double-blind, placebo-controlled trials with a total of 878 participants were included. Both risperidone and aripiprazole significantly reduced ABC Irritability scores compared with placebo. Risperidone and aripiprazole had similar efficacy.

With regard to restricted and repetitive behaviors as a core symptom of ASD, two recent meta-analyses have examined the effects of pharmacological treatments. A meta-analysis that included 552 participants with ASD in nine RCTs found that none of the medications (fluvoxamine, risperidone, fluoxetine, citalopram, oxytocin, NAC, buspirone) significantly differed from placebo in their effects on restricted and repetitive behavior outcomes (Y. Yu *et al.* 2020).

Another meta-analysis on the pharmacological treatment of restricted and repetitive behaviors in autism included 64 randomized placebo-controlled trials including 3,499 participants with ASD (Zhou *et al.* 2021). Antipsychotics significantly improved restricted and repetitive behaviors compared with placebo, although the effect size was small. Larger significant positive effects on restricted and repetitive behaviors were shown in individual studies of fluvoxamine, buspirone, bumetanide, divalproex, guanfacine, and folinic acid, but these studies have not been replicated. Other pharmacological treatments including oxytocin, omega-3 fatty acids, SSRIs, and methylphenidate did not significantly reduce restricted and repetitive behavior compared with placebo.

Clinical Recommendations for Autism Spectrum Disorder

Although there is no evidence that pharmacotherapy is effective in treating the core social and communication deficits in ASD, medications have been shown to be useful in treating associated symptoms, such as hyperactivity, inattention, stereotypies, self-injurious behavior, tantrums, aggression, mood lability, and anxiety. Antipsychotics may decrease withdrawal, stereotypies, and aggression and may facilitate learning. Most available data support the use of risperidone or aripiprazole for treating irritability, aggression, self-injurious behavior, temper tantrums, and mood lability associated with ASD in children and adolescents. Serotonin reuptake inhibitors and other antidepressants have been shown to reduce compulsions, anxiety, and depression in children with ASD. Other agents that may be beneficial in treating associated symptoms are a_2 agonists, stimulants, mood stabilizers, and norepinephrine reuptake inhibitors (Volkmar *et al.* 2014).

Limited data are available on the long-term use of pharmacotherapy in children with ASD. After receiving an intermediate-length (4-to 6-month) course of treatment with risperidone, children withdrawn from the medication through placebo substitution had high relapse rates (Research Units on Pediatric Psychopharmacology Autism Network 2005; Troost *et al.* 2005). Therefore, clinicians must weigh the risk-benefit ratio of maintenance medication treatment in this population and carefully monitor children for side effects.

Conclusion

The evidence base for medication treatment of child and adolescent psychiatric disorders continues to grow. More clinical trials are needed to assess the efficacy and safety of medication augmentation strategies, as well as the optimal duration of treatment. The goal of appropriate psychopharmacological management is not only to reduce acute symptoms but also to prevent long-term impairment in children and adolescents.

APPENDIX

Psychotropic Medications Commonly Prescribed for Children and Adolescents

This appendix describes common classes of psychotropic medications used to treat children and adolescents. Dosing information, monitoring schedules, and common side effects are presented for each medication class.

Antidepressants

Dosage and Monitoring

The starting dosages and target dosages of antidepressants for children and adolescents are listed in Table 60-1. Premedication laboratory testing should include complete blood count, blood chemistries, and liver function tests. Blood pressure should be monitored during dosage titration with venlafaxine. The U.S. Food and Drug Administration (2007) issued the following black box warning, which applies to all antidepressants:

TABLE 60-1. Clinical use of antidepressants in children and adolescents

Medication	Typical starting dosage (mg) Child	Typical starting dosage (mg) Adolescent	Target dosage (mg/day)
Selective serotonin reuptake inhibitors			
Citalopram	5-10	10	20-40
Escitalopram	5	10	10-20
Fluoxetine	5-10	10	20-40
Paroxetine[a]	5-10	10	20-40
Sertraline	25	50	100-200
Mirtazapine	15	15	30-45
Venlafaxine[b]	37.5	37.5	150-225
Bupropion[a]	37.5 bid	37.5 bid	100-300
Duloxetine	30	30	60-120
Desvenlafaxine	25	25	25-25

[a] Immediate-release hydrochloride salt.

[b] Extended-release hydrochloride salt capsule.

> Antidepressants increased the risk compared to placebo of suicidal thinking and behavior (suicidality) in children, adolescents, and young adults in short-term studies of major depressive disorder (MDD) and other psychiatric disorders. Anyone considering the use of [Name of Antidepressant] or any other antidepressant in a child, adolescent, or young adult must balance this risk with the clinical need. Short-term studies did not show an increase in the risk of suicidality with antidepressants compared with placebo in adults beyond age 24 years; there was a reduction in risk with antidepressants compared with placebo in adults ages 65 years and older. Depression and certain other psychiatric disorders are themselves

> associated with increases in the risk of suicide. Patients of all ages who are started on antidepressant therapy should be monitored appropriately and observed closely for clinical worsening, suicidality, or unusual changes in behavior. Families and caregivers should be advised of the need for close observation and communication with the prescriber.

Side Effects

Common side effects of SSRIs are headache, nausea, abdominal pain, dry mouth, insomnia, and somnolence (Emslie *et al.* 2002; Keller *et al.* 2001; Wagner *et al.* 2003a, 2004b, 2006a). Potential serious adverse events include serotonin syndrome, EPS (tics, myoclonus), amotivational syndrome, and increased bleeding (Hammerness *et al.* 2006). A major advantage of SSRIs is their safety in overdose (Barbey and Roose 1998).

Common side effects of mirtazapine are somnolence, increased appetite, weight gain, dizziness, dry mouth, and constipation (Green 2001).

Common side effects of venlafaxine include anorexia, abdominal pain, insomnia, somnolence, dizziness, dry mouth, increased sweating and nervousness, and elevated blood pressure with dosage increase (Emslie *et al.* 2007; Green 2001).

Common side effects of bupropion are headache, nausea, rash, irritability, drowsiness, fatigue, and anorexia (Barrickman *et al.* 1995; Conners *et al.* 1996; Daviss *et al.* 2001). Bupropion is contraindicated in children with seizure disorders, because it may lower the seizure threshold.

Common side effects of duloxetine are nausea, vomiting, nasopharyngitis, abdominal pain, headache, and somnolence (Atkinson *et al.* 2014; Emslie *et al.* 2014).

Common side effects of desvenlafaxine are headache, abdominal pain, nausea, and dizziness (Atkinson *et al.* 2014; Weihs *et al.* 2018).

In a network meta-analysis of antidepressants for MDD in children and adolescents, fluoxetine was more tolerable than duloxetine. Venlafaxine-and duloxetine-treated youths had more discontinuations due to adverse events than those given placebo (Cipriani *et al.* 2016).

In a large-scale systematic meta-review that included six antidepressants (sertraline, escitalopram, paroxetine, fluoxetine, venlafaxine, and vilazodone), fluoxetine and escitalopram had more favorable safety profiles than other antidepressants in children and adolescents (Solmi *et al.* 2020).

Atypical Antipsychotics

Dosage and Monitoring

The usual starting dosages and target dosages of atypical antipsychotics are listed in Table 60-2. Premedication laboratory testing should include complete blood count, blood chemistries, and liver function tests. In addition, the recommendations of the American Diabetes Association *et al.* (2004) should be followed. Baseline measures should be obtained for BMI, waist circumference, blood pressure, and fasting glucose and lipid panels. BMI should be followed monthly for 3 months and then measured quarterly. Blood pressure, fasting glucose, and lipid panels should be followed up at 3 months and then yearly. Monitoring should also be done for EPS.

TABLE 60-2. Clinical use of atypical antipsychotics in children and adolescents

Medication	Typical starting dosage (mg)	Target dosage (mg/day)
Clozapine*	12.5-25 bid	200-500
Olanzapine	2.5 bid	10-20
Quetiapine IR	25-50 bid	400-800
Quetiapine XR	50 bid	400-800
Risperidone	0.25 bid	1-3
Ziprasidone*	20 bid	80-120

Note. ER = extended release; IR = immediate release; XR = extended release.

*Off-label use (Safety and effectiveness in pediatric patients have not been established).

Source. Adapted from Kowatch and DelBello 2006.

Medication	Typical starting dosage (mg)	Target dosage (mg/day)
Aripiprazole	2.0-5.0 hs	10-30
Asenapine	2.5 sublingually bid	2.5-10 sublingually bid
Paliperidone ER		
Weight < 51 kg	3	3-6
Weight [?] 51 kg	3	3-12

Note. ER = extended release; IR = immediate release; XR = extended release.
*Off-label use (Safety and effectiveness in pediatric patients have not been established).
Source. Adapted from Kowatch and DelBello 2006.

Side Effects

Side effects of atypical antipsychotics include weight gain, dyslipidemia, insulin resistance and diabetes, hyperprolactinemia, EPS and akathisia, QTc prolongation, sedation, liver toxicity, neutropenia, and neuroleptic malignant syndrome. Clozapine has also been associated with seizures, agranulocytosis, and myocarditis (Correll *et al.* 2006).

In a large-scale systematic meta-review that included eight antipsychotics (risperidone, quetiapine, aripiprazole, lurasidone, paliperidone, ziprasidone, olanzapine, and asenapine), lurasidone had a more favorable safety profile than the other antipsychotics in children and adolescents (Solmi *et al.* 2020). Of the antipsychotics, the most safety concerns were with olanzapine for children and adolescents.

In a systematic review and meta-analysis of antipsychotics (aripiprazole, asenapine, paliperidone, risperidone, quetiapine, olanzapine, molindone, and ziprasidone) in children and adolescents with schizophrenia spectrum disorders, weight gain was associated primarily with olanzapine, EPS and akathisia with molindone, and prolactin increase with risperidone, paliperidone, and olanzapine (Pagsberg *et al.* 2017b).

Mood Stabilizers

Dosage and Monitoring

The starting dosages, target dosages, and therapeutic serum levels of mood stabilizers are listed in Table 60-3. Premedication laboratory testing in general should include complete blood count, liver function tests, and a pregnancy test (for female patients).

TABLE 60-3. Clinical use of mood stabilizers in children and adolescents

Medication	Typical starting dosage (mg)	Target dosage	Therapeutic serum level
Carbamazepine	7 mg/kg/day	Based on response and serum level	8-11 mg/L
Lamotrigine	12.5 mg/day	Based on response	N/A
Lithium	25 mg/kg/day[b]	30 mg/kg/day[b]	0.8-1.2 mEq/L
Oxcarbazepine	150 mg bid	20-29 kg: 900 mg/day[a] 30-39 kg: 1,200 mg/day[a] > 39 kg: 1,800 mg/day[a]	N/A
Topiramate	25 mg/day	100-400 mg/day	N/A
Valproic acid, divalproex	20 mg/kg/day[a]	20 mg/kg/day[b]	90-120 mg/mL

Note. N/A = not applicable.

[a] Divided into 2 daily doses.

[b] Divided into 2-3 daily doses.

Source. Adapted from Kowatch and DelBello 2006.

For lithium, baseline thyroid function tests, electrolytes, urinalysis, blood urea nitrogen, creatinine, and serum calcium should also be obtained. Lithium levels, renal function, thyroid function, and urinalysis should be monitored every 3-6 months.

For patients taking divalproex, drug serum levels, complete blood count, and liver function tests should be monitored every 3-6 months. Because of concerns about a possible relationship between divalproex and polycystic ovary syndrome (PCOS; Rasgon 2004), female adolescents taking divalproex should be monitored for signs of PCOS, including menstrual abnormalities, weight gain, acne, and hirsutism (DelBello and Kowatch 2006; McClellan *et al.* 2007). Parents and their female adolescents should be apprised about this possible association before initiating medication.

For oxcarbazepine, children should be monitored for hyponatremia.

Side Effects

Common side effects of lithium in children and adolescents include hypothyroidism, nausea, polyuria, polydipsia, acne, tremor, and weight gain (DelBello and Kowatch 2006).

Common side effects of divalproex in children and adolescents include weight gain, nausea, sedation, and tremor (DelBello and Kowatch 2006). Concerns have been raised about a possible association between divalproex and PCOS (Rasgon 2004). Other potential adverse effects of concern are hepatic failure, pancreatitis, thrombocytopenia, behavioral deterioration, and hair loss (Davanzo and McCracken 2000; Green 2001).

Side effects of topiramate include decreased appetite, weight loss, nausea, diarrhea, paresthesias, somnolence, and word-finding difficulties (DelBello and Kowatch 2006; DelBello *et al.* 2005).

Side effects of oxcarbazepine in children include dizziness, nausea, somnolence, diplopia, fatigue, and rash (Wagner *et al.* 2006b). Hyponatremia is also a side effect of oxcarbazepine.

Common side effects of lamotrigine in children include ataxia, nausea, vomiting, and constipation. Of particular concern, the incidence of serious rash, including Stevens-Johnson syndrome, in pediatric populations is reported to be 1%. This high incidence of serious rash may be attributable to prior use of high dosages of lamotrigine with concomitant divalproex (Messenheimer 1998). The current dosing guidelines may reduce this rash incidence in pediatric patients.

A large-scale systematic meta-review of the safety of antidepressants, antipsychotics, anti-ADHD medications, and mood stabilizers in children and adolescents included two mood stabilizers (valproate and lithium). Lithium showed a more favorable safety profile than valproate in children and adolescents (Solmi *et al.* 2020).

Atomoxetine

Dosage and Monitoring

Atomoxetine can be taken in the late afternoon or evening, whereas stimulants generally cannot; atomoxetine may have less pronounced effects on appetite and sleep than stimulants, although it may produce more nausea or sedation. Gastrointestinal distress can be minimized by taking the medication after a meal. In children and young adolescents, atomoxetine is initiated at a dosage of 0.3 mg/kg/day and titrated over 1-3 weeks to a maximum dosage of 1.2-1.8 mg/kg/day (Kratochvil *et al.* 2003). In adults or adult-sized adolescents, atomoxetine should be started at 40 mg/day and titrated to 80-100 mg/day over 1-3 weeks, if needed (Kratochvil *et al.* 2003). Atomoxetine's labeling recommends either once-daily or twice-daily dosing, although atomoxetine's elimination half-life of 5 hours (as well as clinical experience) suggests that twice-daily dosing (early morning and early evening) is more effective and less likely to cause side effects. Michelson *et al.* (2002) showed that although atomoxetine

was superior to placebo at week 1 of the trial, its greatest effects were observed at week 6, suggesting that patients should be maintained at the full therapeutic dosage for at least several weeks for the drug to reach its full effects.

Side Effects

Side effects that occurred at higher rates with atomoxetine than with placebo in clinical trials included gastrointestinal distress, sedation, and decreased appetite. These effects can generally be managed by dosage adjustment and often attenuate with time. Since 2005 the label for atomoxetine has carried a black box warning regarding rare cases of suicidal ideation, but a large retrospective cohort study involving more than 250,000 patients showed no increased risk of suicidal ideation in those treated with atomoxetine relative to those treated with stimulants (Linden *et al.* 2016).

Alpha-2 Adrenergic Receptor Agonists

Dosage and Monitoring

The initial starting and target dosages for both clonidine and guanfacine are shown in Table 60-4.

TABLE 60-4. Titrations of alpha-2 agonists

	Typical starting dosage (mg)		
Medication	**Child**	**Adolescent**	**Target dosage (mg/day)**
Guanfacine IR	0.5 hs	1 hs	1-4
Guanfacine XR	1	1	1-4
Clonidine IR	0.05	0.1	0.2-0.4 (divided into 3 or 4 daily doses)
Clonidine XR	0.1	0.2	0.1-0.4 (divided into 2 daily doses or a higher dose at bedtime)

Note. IR = immediate release; XR = extended release.

Side Effects

Pooling of all adverse events reported in clinical trials of a_2 agonists showed that rates of fatigue, sedation, and somnolence were significantly higher with these medications than with placebo (Hirota *et al.* 2014). Sedation tends be much more common with clonidine than with guanfacine. Data from five studies of a_2 agonists showed no significant differences in blood pressure with guanfacine, but clonidine immediate release was associated with a mean drop of 5.2 mm Hg in systolic blood pressure. a_2 Agonists may be associated with an increase in the QTc interval (Hirota *et al.* 2014). In the 1990s, concerns were raised about isolated cases of sudden death, particularly in children taking clonidine in combination with methylphenidate, but these concerns have not persisted, as subsequent studies of a_2 agonists in the treatment of ADHD have not reported any serious cardiovascular adverse effects (Fay and Alpert 2019a, 2019b; Martinez-Raga *et al.* 2013). Therefore, routine electrocardiogram (ECG) monitoring in patients without any cardiac history is not necessary.

Psychostimulants

Dosage and Monitoring

A wide variety of stimulant preparations are available; Table 60-5 describes their use in clinical practice. Each stimulant has a maximum dosage suggested by the FDA-approved package insert, but higher off-label dosages are commonly used with careful monitoring. For safety monitoring, a patient's pulse, blood pressure, weight, and height should be obtained at baseline and at least annually. No laboratory measures or ECG monitoring is required.

TABLE 60-5. Clinical use of psychostimulants in children and adolescents

Medication	Dosage strengths	Typical starting dosage	FDA maximum/day	Off-label maximum/day

Medication	**Dosage strengths**	**Typical starting dosage**	**FDA maximum/day**	**Off-label maximum/day**
Amphetamine preparations				
Adderall	5, 7.5, 10, 12.5, 15, 20, 30 mg	3-5 yr: 2.5 mg qd [?] 6 yr: 5 mg qd-bid	40 mg	[?] 50 kg: 60 mg

Adhansia XR[a]	--[a]			
Aptensio XR	10, 15, 20, 30, 40, 50, 60 mg	10 mg qam	60 mg	ND
Jornay PM	20, 40, 60, 80, 100 mg	20 mg (take in evening between 6:30 and 9:30 P.M.)	100 mg	ND
Cotempla XR	8.6, 17.3, 25.9 mg	8.6-17.3 mg	51.8 mg	ND

Note. CD = controlled delivery (extended release); ER = extended release; LA = long acting (extended release); ND = not determined; SR = sustained release; XR = extended release.

[a] Brand-name product removed from the U.S. market.

Source. PDR Network LLC: PDR Prescribers' Digital Reference (https://www.pdr.net/). Whippany, NJ, ConnectiveRx, n.d. Accessed July 1, 2023. Stevens JR, Wilens TE: "Stimulant Medication in Children and Adolescents," in *Attention-Deficit Hyperactivity Disorder in Adults and Children*. Edited by Adler LA, Spencer TJ, Wilens TE. Cambridge, UK, Cambridge University Press, 2015, pp. 245-258.

Side Effects

Stimulant adverse effects commonly include immediate short-term effects such as insomnia (12.3%), headaches (14.5%), and reduced appetite (28.6%) (Cerrillo-Urbina *et al.* 2018). These are generally self-limited and resolve within a month, but they can make a child so uncomfortable as to result in discontinuation. Emotional side effects are more rare; the issue is confounded by the fact that stimulants often improve the mood lability that is often associated with ADHD. Meta-analyses suggest that overall, methylphenidate reduces mood lability, whereas amphetamine may have a slight tendency to increase it (Pozzi *et al.* 2018). If a child shows a distinct worsening of mood after starting a stimulant, that agent should be discontinued, but this does not preclude a trial of an alternative stimulant.

In one study, stimulants induced very modest increases in blood pressure and pulse, with no differences in the number of adverse cardiac events between participants receiving methylphenidate treatment and those receiving placebo (Dalsgaard *et al.* 2014). A meta-analysis of three studies with 775 adults also found no significant difference in adverse cardiac events between methylphenidate and placebo (E. F. Liang *et al.* 2018), nor was methylphenidate associated with a higher risk of all-cause death, heart attack, or stroke (Liu *et al.* 2019). Routine ECG monitoring of patients who do not have a cardiac disease history is not necessary when treating ADHD with stimulants (Fay and Alpert 2019a, 2019b).

A review of 109 studies concluded that the nonmedical use of prescribed stimulants is a significant public health problem, especially in college students, despite the fact that stimulants may not improve academic performance in individuals without ADHD (Faraone *et al.* 2020). Common methods of diversion include obtaining prescriptions from multiple prescribers or filling prescriptions at multiple pharmacies, and such behaviors were four times more common in the ADHD group than in a comparison group of patients with asthma (Cepeda *et al.* 2014).

The effect of stimulants on growth has been the subject of multiple long-term studies. The most recent meta-analysis (Carucci *et al.* 2020) suggests that long-term use of stimulants is associated with minor impacts on height and weight in children and adolescents with ADHD (pre/post difference for height Z score, SMD = 0.27; weight Z score, SMD = 0.35). Although such an effect could reduce mean height gain by approximately 1.39 cm and weight gain by approximately 1.96 kg for a 10-year-old boy over a 2-year period, the growth effect appears to plateau by late adolescence. Thus, ultimate height and weight effects may be quite small at the individual level and not clinically significant.

Viloxazine

Dosage

In children ages 6-11 years, the recommended starting dosage for viloxazine is 100 mg once daily. Viloxazine may be titrated in increments of 100 mg weekly to the maximum recommended dosage of 400 mg once daily. For adolescents ages 12-17 years, the clinician should start at 200 mg once daily; the dosage may be increased after 1 week, by an increment of 200 mg, to the dosage of 400 mg once daily. The capsules may be swallowed whole or opened and the entire contents sprinkled onto applesauce.

Side Effects

In clinical trials, viloxazine was well tolerated; adverse events that occurred at rates significantly greater than those of placebo were somnolence (14%), decreased appetite (7.7%), fatigue (7.2%), headache (6.8%), and upper abdominal pain (4.8%). Severe adverse events were rare and were not different between the placebo and viloxazine groups. There were no clinically meaningful changes in ECG, vital signs, or laboratory measures.

CHAPTER 61

Treatment During Late Life

Katharine K. Brewster, M.D.
Bret R. Rutherford, M.D.
Steven P. Roose, M.D.

Adverse events caused by medication are a significant cause of morbidity and mortality in older adults. In a large study of ambulatory Medicare enrollees, 38% of adverse drug events were serious, life-threatening, or fatal, and 28% were considered preventable (Gurwitz *et al.* 2003). Moreover, psychotropics are among the most common medications associated with preventable adverse drug events in elderly patients in long-term care settings (Davies and O'Mahony 2015).

Pharmacokinetics of Psychotropic Medications in Older Adults

Age-associated pharmacokinetic differences may be due to changes in absorption, distribution, metabolism, or elimination of a drug (Table 61-1). In general, age-associated pharmacokinetic changes result in higher and more variable drug concentrations. Although individuals older than 65 years account for more than one-half of prescription drug expenditures in the United States, they are often excluded from clinical and regulatory trials. The trials that do include older adults rarely include the "oldest old" (i.e., 85+ years), those with multiple comorbidities, or those taking multiple medications, and these omissions raise questions about the generalizability of psychotropic data to the frail elderly. Therefore, specific information on the pharmacokinetics of most psychoactive medications is inadequate, particularly regarding medical comorbidities and potential drug interactions. The limited information that does exist for older subjects is largely derived from traditional pharmacokinetic studies, which usually are not adequate to rule out the possibility of nonlinear kinetics.

TABLE 61-1. Physiological changes in older adults associated with altered pharmacokinetics

Organ system	Change	Pharmacokinetic consequence
Gastrointestinal tract	Decreased intestinal and splanchnic blood flow	Decreased rate of drug absorption
Circulatory	Decreased concentration of plasma albumin and increased a_1-acid glycoprotein	Increased or decreased free concentration of drugs in plasma
Kidney	Decreased glomerular filtration rate	Decreased renal clearance of active metabolites
Muscle	Decreased lean body mass and increased adipose tissue	Altered volume of distribution of lipid-soluble drugs, leading to increased elimination half-life
Liver	Decreased liver size; decreased hepatic blood flow; minimal effects on cytochrome P450 enzyme activity	Decreased hepatic clearance

Absorption

Although absorption of nutrients is often impaired in older persons, the rate and extent of passive drug absorption are not affected by normal aging. However, antacids and high-fiber supplements may significantly diminish the absorption of medications.

Distribution

Because a drug's half-life is directly proportional to its apparent volume of distribution, loss of lean body mass with aging will result in longer half-lives and drug accumulation for most lipid-soluble psychotropics. Conversely, for water-soluble drugs (e.g., lithium and digoxin), volumes of distribution will be diminished in older patients, reducing the margin of safety after acute increases in plasma drug concentration.

Reductions in serum albumin with age and increases in a_1-acid glycoprotein with illness may affect the extent of drug bound to plasma proteins. However, changes in plasma protein binding are of clinical significance only when therapeutic drug monitoring is used to adjust dosing, because total drug concentrations (free + protein bound) are usually reported (Benet and Hoener 2002). Therefore, total drug levels may be interpreted as too low if a drug's free fraction is increased by diminished plasma proteins or drug displacement.

Metabolism

Available evidence suggests that there is no uniform age-associated decline in liver metabolism by cytochrome P450 (CYP) enzymes (Schmucker 2001). Nonetheless, reductions in hepatic mass and blood flow with aging place greater emphasis on interindividual differences in drug metabolic capacity that may be due to genetics or medication interactions.

In recent years, pharmacogenetic testing has become increasingly available for clinicians, and such instruments may be used to genetically guide treatment with psychotropic medications. Among the many pharmacogenetic tests that have been proposed, genetic variation in

CYP2D6 enzymes can most clearly affect pharmacokinetic parameters but does not obviously affect antidepressant treatment response. According to guidelines put forth by the International Society of Psychiatric Genetics, there is inconclusive evidence to support widespread use of pharmacogenomic tests other than *HLA-A* and *HLA-B* prior to the use of carbamazepine and oxcarbazepine. However, genetic information for *CYP2D6* and *CYP2C19* would likely be most beneficial for persons who have experienced an inadequate response or an adverse reaction to a previous antidepressant or antipsychotic trial (International Society of Psychiatric Genetics 2019). Therefore, the Clinical Pharmacogenetics Implementation Consortium recommends dosing based on *CYP2D6* and *CYP2C19* genotypes for tricyclic antidepressant (TCA) and selective serotonin reuptake inhibitor (SSRI) medications in adults (Hicks *et al.* 2017). However, further studies are needed to validate evidence for these recommendations in older adults.

CYP2D6 and CYP2C19 are the enzymes responsible for metabolizing 50%-60% of all antidepressants as well as many antipsychotics (Marshe *et al.* 2020). Frequency differences for known *CYP2D6* polymorphisms vary across ethnic and racial groups and are more common in white individuals (5%-10% of whites are poor metabolizers of CYP2D6) (de Leon *et al.* 2006). A few studies have examined the effect of CYP2D6 metabolization on drug plasma levels and metabolite concentration levels in older adults (Marshe *et al.* 2020). For example, plasma levels of venlafaxine have been found to be associated with genetically determined CYP2D6 enzyme activity in older adults with depression (Whyte *et al.* 2006). However, there is limited evidence that CYPD26 metabolism alters the dosing of antidepressant medications (Bijl *et al.* 2008) and no evidence that enzymatic activity affects response to antidepressant treatment in older adults (Marshe *et al.* 2020).

In parallel, CYP2C19 metabolizes several antidepressants, such as citalopram, escitalopram, and amitriptyline. Poor metabolizers of CYP2C19 are common and account for up 25% of East Asians (de Leon *et al.* 2006), but there is limited information regarding the pharmacokinetic effects of *CYP2C19* polymorphisms for antidepressants. One analysis found that among CYP2C19 poor metabolizers, adults older than 65 years had a 1.4-fold higher mean escitalopram concentration compared with younger adults

(< 40 years), but this difference did not reach statistical significance (Waade *et al.* 2014).

Drugs metabolized by CYP3A4, such as alprazolam, clonazepam, carbamazepine, and mirtazapine, appear to be cleared less well in elderly patients (Ronfeld *et al.* 1997). However, this may be because metabolism of CYP3A4-metabolized drugs is typically perfusion-limited (i.e., dependent on hepatic blood flow, which can decline with age). CYP3A4 is substantially responsible for the "first-pass," or presystemic, drug disposition, as it makes up 30% of total hepatic CYP and nearly all drug-metabolizing enzyme in the small bowel (Shimada *et al.* 1994). CYP3A4 activity may be inhibited by fluvoxamine, fluoxetine, grapefruit juice, protease inhibitors, macrolide antibiotics, and triazole antifungals. The CYP3A4 enzyme is also potently induced by other drugs, such as carbamazepine, phenytoin, topiramate, modafinil, barbiturates, steroids, and St. John's wort, which may increase the likelihood of therapeutic failure for concurrently prescribed CYP3A4 substrate drugs.

CYP1A2 metabolizes clozapine, olanzapine, and fluvoxamine and contributes to the demethylation of some tertiary TCAs. This enzyme is induced by cigarette smoking, cruciferous vegetables, and charcoal-broiled meat. For example, abrupt cessation of smoking can increase clozapine levels and elevate the risk of toxicity.

Excretion

Age-associated decline in renal clearance may affect excretion of psychotropic drug metabolites and lithium in older patients. The magnitude of this decline varies greatly among the aged, being exacerbated by concomitant conditions (e.g., diabetes and hypertension) and medications (e.g., nonsteroidal anti-inflammatory drugs). Renal clearance of TCA metabolites can be reduced by normal aging, accounting for increased risk of toxicity (Pollock *et al.* 1992). Higher concentrations of bupropion and venlafaxine metabolites also have been observed in older patients and those with renal impairment, with uncertain clinical consequences.

Pharmacodynamics of Psychotropic Medications in Older Adults

Interindividual differences in pharmacodynamics become evident when those with similar plasma drug concentrations experience different effects. In general, older individuals are more sensitive to adverse effects of psychotropics at lower concentrations. Homeostatic mechanisms (e.g., postural control, water balance, orthostatic circulatory responses, and thermoregulation) are frequently less robust in older adults and may interfere with the ability to physiologically adapt to medication.

For this reason, all antidepressants may increase the risk of falls and hip fractures, although recent literature has raised questions about the strength of this association (Brannstrom *et al.* 2019). Similarly, the syndrome of inappropriate antidiuretic hormone secretion has been reported as an age-associated adverse effect of SSRIs (Kirby and Ames 2001). Reductions in dopamine or acetylcholine function with age may increase an individual's sensitivity to antipsychotics and SSRIs as well as to medications with antimuscarinic effects (Graff-Guerrero *et al.* 2015). For example, use of anticholinergic medications is associated with an increased risk for cognitive dysfunction and brain atrophy (Risacher *et al.* 2016), although these agents continue to be widely prescribed in older patients (Grossi *et al.* 2020).

Anticoagulant-antidepressant interactions may be both pharmacokinetic and pharmacodynamic. Fluvoxamine and fluoxetine pose the greatest risk of pharmacokinetic interactions through CYP2C9 inhibition, reducing the clearance of warfarin's active *S*-enantiomer. However, increased bleeding times with SSRIs alone or in combination with anticoagulants or nonsteroidal anti-inflammatory drugs also may be possible as a result of the effect of these medications in depleting platelets of serotonin and attenuating their aggregation (Pollock *et al.* 2000b; Shin *et al.* 2015).

At present, there exists only preliminary evidence that genetic differences may influence pharmacodynamics in older patients. For example, polymorphisms in genes encoding serotonin transporters, norepinephrine transporters, and brain-derived neurotrophic factor have been suggested to contribute to patient variability in antidepressant effects (Marshe *et al.* 2020). Several studies have shown that the homozygous

genotype of the long-long (LL) serotonin transporter promoter genotype is associated with better treatment outcomes with SSRIs in younger and older adults (Fabbri and Serretti 2015; Serretti *et al.* 2006). For example, depressed elderly patients with the LL serotonin transporter promoter genotype were found to have a more rapid initial response to paroxetine (Pollock *et al.* 2000a). However, an analysis of late-life depression in Korea found the opposite result--that is, better responses among carriers of the short (S) allele (Kim *et al.* 2006).

Antidepressants in Older Adults

Late-Life Depression

In cross-sectional surveys, only 3% of community-dwelling adults older than 60 years have symptoms that meet criteria for a current major depressive episode (NIH Consensus Conference 1992), but 15% of older adults have clinically significant depressive symptoms (Rothschild 1996). Such subthreshold symptomatology is important given its deleterious consequences, which include increasing an older adult's risk of disability, increasing mortality in patients with heart disease, and being associated with high rates of completed suicide in individuals older than 65 years. Compounding this public health burden are the facts that late-life depression is highly recurrent, can become chronic (Alexopoulos *et al.* 1996), and is often difficult to treat (Sneed *et al.* 2008).

Late-life neuropsychiatric disorders are increasingly recognized as the products of complex interactions between psychopathology and aging processes affecting brain structure and function. Thus, late-life depression is hypothesized to be a collection of subtypes distinguished from each other by their relationships to distinct aging processes, underlying biomarkers, salient behavioral manifestations, clinical characteristics, and treatment responsivity.

Vascular depression is a proposed subtype of late-life depression that is characterized by vascular lesions in deep white matter tracts that disconnect prefrontal cortical regions from striatal and limbic areas, causing depressive symptoms and executive dysfunction.

A second proposed subtype, *depression with slowing*, is believed to result from the age-dependent increase in inflammation (called "inflammaging"). One such adverse effect of inflammaging concerns dopaminergic functioning, which declines linearly with age and is implicated in the development of psychomotor slowing. Studies have established an association between inflammation-induced dopaminergic dysfunction and the development of depressed mood, anhedonia, and deficient reward processing (Capuron *et al.* 2012; Felger and Miller 2012; Raison *et al.* 2006). Psychomotor slowing (as evidenced by decreased gait speed) may increase stress, impair function, and decrease activity levels and may represent an intermediate step on a pathway to late-life depression. Furthermore, slowed processing speed not only is a negative prognostic factor in antidepressant treatment but also places older individuals on an unhealthy aging trajectory characterized by poor health outcomes (Taylor *et al.* 2006).

Depression related to frailty is a third proposed subtype of late-life depression, because fatigue is a cardinal feature of depression and a core characteristic of the syndrome of frailty (weakness, decreased activity levels, slowed gait speed, and unintentional weight loss) (Bandeen-Roche *et al.* 2006; Fried *et al.* 2001). Given that mitochondria produce most of the body's energy, age-related decline in mitochondrial output constitutes part of the biological basis for the physical and mental fatigue and the pathophysiology of the frailty-associated subtype. Declining mitochondrial output may underlie the cognitive impairment, slowing, and fatigue that are characteristic of late-onset depression. Such qualities may help to explain the heterogeneity of late-onset depression and why its diverse symptoms do not respond as well to antidepressant medication, a treatment that does not target any of these pathologies.

Antidepressant Treatment in Older Patients

Variability in results of randomized controlled trials of antidepressants in late-life depression may result from heterogeneity in the patient population and study design. The standard considerations in study design--namely, randomization, placebo versus comparator control, dosage, duration, and criteria for response and remission--are all important, but specifically the value of placebo-controlled trials versus comparator trials and optimal duration of treatment have been systematically reexamined. Sneed *et al.* (2008) conducted a meta-analysis of all studies published in peer-reviewed journals from 1985 to 2006 that were randomized placebo-controlled or comparator (a comparison of two active conditions) trials of antidepressants for the treatment of late-life depression. The intent of the meta-analysis was to determine whether rates of response to medications in comparator trials are significantly higher than rates of response to comparable medications in placebo-controlled trials--that is, whether study design significantly affects treatment outcome. Sixteen studies (nine comparator trials and seven placebo-controlled trials) met the rigorous inclusion criteria for the meta-analysis. As hypothesized, antidepressant response rates were significantly higher in the comparator trials compared with placebo-controlled trials; the estimated probability of antidepressant response in a placebo-controlled trial was 46% as compared with 60% in a comparator trial. The results of the study suggest that when clinicians want to make evidence-based treatment decisions and communicate likelihood of response to patients, data from comparator trials may be more appropriate than results of placebo-controlled trials.

Tricyclic Antidepressants

Although perhaps used much less in younger patients, the TCAs, specifically nortriptyline, continue to be an important option in the treatment of late-life depression. Although the preponderance of studies examining TCA treatment in late-life depression do not use plasma level measurements, the findings of these studies have established TCAs to be an effective treatment for depression in older adults.

Nortriptyline.

Of the TCAs, nortriptyline has been found to induce the least orthostatic hypotension and has a documented "therapeutic window" that permits optimal dosing (Roose *et al.* 1981). Consequently, nortriptyline has emerged as the choice of this class of medications for late-life depression. However, there are no rigorous placebo-controlled trials of nortriptyline in late-life depression; thus, the relative effectiveness of this medication is inferred from two open trials and three randomized comparator trials.

In a study reported by Flint and Rifat (1996), 101 patients with symptoms meeting DSM-III-R criteria for major depressive disorder (MDD) (American Psychiatric Association 1987) were treated openly with nortriptyline. The dosing schedule was as follows: all patients achieved a daily dosage of 75 mg by the end of week 1, and then the dosage was adjusted, if necessary, to achieve a plasma level within the therapeutic window of 50-150 ng/mL. The treatment duration was 6 weeks, and the remission criterion was a 17-item Hamilton Rating Scale for Depression (Ham-D-17) final score of 10 or less; 60% of the intent-to-treat sample and 75% of the completers met the remission criterion. To establish speed of response, the authors determined the week of treatment that the 61 patients who met the criterion for remission at the end of the study first achieved sustained remission. Not surprisingly, at the end of week 1, no patient met the criterion for remission, and thus the cumulative response rate was 0%. At week 2, 11% of the sample met the remission criterion, and at week 3, 33% met the remission criterion (thus, the cumulative rate at the end of week 3 was 11% + 33%, or 44%). At weeks 4 and 5, 25% and 20%, respectively, met the remission criterion. Thus, the accumulated remission rate at the end of week 5 was 89%. Although it is widely believed that individuals with late-life depression should have longer treatment trials, specifically 12 weeks, this study found that 89% of the patients who eventually recovered did so by the end of week 5. A second open study of a therapeutic plasma level of nortriptyline reported on 42 inpatients (mean age = 70 years) with cardiac disease and melancholic depression who also were treated for 6 weeks (Roose *et al.* 1994). The remission criterion was a 21-item Ham-D (Ham-D-21) final score of 8 or less; the intent-to-treat remission rate was 67%, the completer remission rate was 82%, and the dropout rate was 19%.

Three randomized controlled studies compared nortriptyline with an SSRI, two studies compared nortriptyline at a therapeutic plasma level with paroxetine, and one study compared flexible-dosage nortriptyline with sertraline. Mulsant *et al.* (2001a) compared nortriptyline with paroxetine in 116 inpatients and outpatients (mean age = 72 years) in a 12-week trial. Remission was defined as a final Ham-D-17 score of 10 or less; the intent-to-treat remission rate was 57% for the nortriptyline group and 55% for the paroxetine group. The rate of dropout due to side effects in the nortriptyline group was significantly higher than that in the paroxetine group (33% vs. 16%; $P = 0.04$).

A second randomized controlled trial comparing nortriptyline (targeted to a therapeutic plasma level) with paroxetine is included in this chapter, although technically it should not be considered a geriatric study because the mean age of the patients was 58 years (Nelson *et al.* 1999). However, it is the only other study comparing a TCA at a therapeutic plasma level with an SSRI, and the results are consistent with those of the Mulsant *et al.* (2001a) study. In this trial, 81 outpatients with ischemic heart disease were treated with medication for 6 weeks. The remission criterion was a final Ham-D-17 score of 8 or less; in the intent-to-treat analysis, 63% of the nortriptyline group and 61% of the paroxetine group were remitters. The dropout rate for nortriptyline (35%) was significantly higher than the dropout rate for paroxetine (10%) ($P < 0.05$). The rate of remission in study completers was 85% for nortriptyline and 68% for paroxetine--a difference that was not statistically significant, although the power of this comparison was limited by the small size of the completer group.

The randomized controlled trial comparing sertraline with nortriptyline included 210 patients (mean age = 68 years) randomly assigned to 12 weeks of medication treatment

(Bondareff *et al.* 2000). Response was defined as a 50% reduction in the 24-item Ham-D (Ham-D-24) score from baseline. Response rates for nortriptyline and sertraline were 41% and 52%, respectively; remission rates were not reported.

TCA side effects and safety. The clinical utility of TCAs in the late-life population is limited by their side-effect and safety profiles. TCAs have significant anticholinergic effects that result in dry mouth, constipation, urinary retention, and confusional states. In addition, TCAs are lethal in overdose, and as little as three times the daily dosage can result in death from heart block or arrhythmias (Glassman *et al.* 1993). The TCAs have type 1A antiarrhythmic activity similar to that of moricizine and quinidine and consequently are presumed to confer an increased risk of sudden cardiovascular death if given to patients with ischemic heart disease. Given the prevalence of occult and manifest ischemic heart disease in individuals older than 60 years, the use of TCAs in this population must reflect a careful consideration of the risk-benefit ratio.

Selective Serotonin Reuptake Inhibitors and Serotonin-Norepinephrine Reuptake Inhibitors

As in younger depressed patients, the SSRIs and serotonin-norepinephrine reuptake inhibitors (SNRIs) are the most commonly prescribed antidepressant classes for late-life depression. Within the SSRI class, the various medications appear to have equivalent efficacy and side-effect profiles. There are differences in pharmacokinetics and potential for drug-drug interactions, which are of importance in the geriatric population and have been discussed earlier in this chapter.

A meta-analysis of 12 placebo-controlled trials of antidepressants, including SSRIs, SNRIs, and bupropion, for the treatment of MDD in patients older than 60 years found an overall odds ratio (OR) of 1.43 (95% CI = 1.24, 1.65; $P < 0.0001$), showing medications to be significantly more effective than placebo; the response rate with medication was 46% compared with 30% for placebo (Nelson 2019; Tedeschini *et al.* 2011). However, there was considerable heterogeneity in treatment response, suggesting that there may be other factors besides the antidepressant medication that could account for the difference in the treatment groups. This meta-analysis reported than the number needed to treat (NNT) between drug and placebo was 10.

While the NNT was developed to facilitate the practice of evidence-based medicine, the use of the NNT to quantify the difference between medication and placebo raises a question about the evidence that can be extended from the clinical trial to the clinical situation. Placebo was assumed to be therapeutically inert in the original formulation of the NNT, but more recent data for conditions such as MDD suggest that assignment to placebo group can have considerable therapeutic effects. The NNT calculated from randomized controlled trials reflects a comparison between medication plus clinical management and placebo plus clinical management, whereas in the clinical setting physicians choose between prescribing open medication, observing a patient over time with a supportive approach, and doing nothing. Thus, NNTs derived from clinical trials are not always relevant to clinical decision-making, because they are based on control conditions that do not exist in standard practice.

Specific medications. ***Fluoxetine.*** Four large studies of fluoxetine in late-life depression have been conducted: 1) a placebo-controlled study (Tollefson *et al.* 1995);

2) a three-cell study comparing venlafaxine, placebo, and fluoxetine (Schatzberg and Cantillon 2000; see "Venlafaxine" below); 3) a randomized controlled trial with a comparator, sertraline (Newhouse *et al.* 2000); and 4) an open-treatment study of fluoxetine (Mesters *et al.* 1992). In the first study, fluoxetine (20 mg/day for 6 weeks) was compared with placebo in 671 patients (Tollefson *et al.* 1995). The intent-to-treat analysis remission rate (Ham-D-17 score [?] 7 after 4 weeks) was 23% for fluoxetine and 13% for placebo; in the completer analysis, the remission rate was 27% for fluoxetine and 16% for placebo. Although fluoxetine was significantly more effective than placebo in both the intent-to-treat and the completer analyses, the remission rates in this study were disappointingly low in comparison to the clinical experience with therapeutic plasma levels of TCAs.

In the comparator randomized clinical trial, patients were randomly assigned to receive either fluoxetine 20-40 mg/day or sertraline 50-100 mg/day for 12 weeks (Newhouse *et al.* 2000). The sample of 225 patients (mean age = 68 years) was somewhat unusual because the mean duration of the current episode of major depressive disorder was 9 years. The intent-to-treat remission rate was 46% for fluoxetine and 45% for sertraline, the completer remission rate was 60% for fluoxetine and 59% for sertraline, and the dropout rate was 33% for fluoxetine and 32% for sertraline. This study also reported an intriguing analysis of the response pattern of a subsample of 75 patients (42 treated with sertraline, 33 treated with fluoxetine) with a mean age of 75 years. For both sertraline and fluoxetine, 95% of the patients who achieved a 50% reduction in baseline Ham-D score did so by the end of week 8. As with the Flint and Rifat (1996) study of a therapeutic plasma level of nortriptyline, these data challenge the clinical wisdom that antidepressant trials in late-life depression must be extended to 12 weeks.

Finally, 308 patients with symptoms meeting DSM-III (American Psychiatric Association 1980) criteria for MDD (mean age: 66 years) were treated openly with 20 mg/day of fluoxetine for 8 weeks (Mesters *et al.* 1992). The remission criterion was a final Ham-D-24 score of 10 or less; the intent-to-treat remission rate was 35%, the completer remission rate was 50%, and the dropout rate was 29%.

***Sertraline*.** In addition to the two randomized controlled comparator trials previously described (nortriptyline vs. sertraline and fluoxetine vs. sertraline), a large rigorous placebo-controlled trial of sertraline in late-life depression was completed (Schneider *et al.* 2003). In this study, 716 patients (mean age = 70 years) were randomly assigned to flexible-dosage sertraline (50-100 mg/day) or placebo in an 8-week clinical trial. The criterion for remission was a final Ham-D-17 score of 10 or less; the intent-to-treat remission rate was 29% in the sertraline group, compared with 23% in the placebo group ($P < 0.05$).

***Paroxetine*.** Two previously described trials, by (Mulsant *et al.* (2001a) and Nelson *et al.* (1999), compared nortriptyline at a therapeutic plasma level with paroxetine, with intent-to-treat remission rates (final Ham-D-17 score [?] 10) for the paroxetine groups of 55% and 61%, respectively. In a third trial, 255 patients (mean age = 72 years) were randomly assigned to receive mirtazapine 30-45 mg/day or paroxetine 30-40 mg/day in an 8-week clinical trial (Schatzberg *et al.* 2002). The criterion for remission was a final

Ham-D-17 score of 7 or less; the intent-to-treat remission rates were 38% for mirtazapine and 28% for paroxetine and were not statistically different.

***Citalopram and escitalopram*.** Many of the studies of citalopram in a geriatric population included patients with depression and dementia or significant cognitive impairment; therefore, the results of these studies are not comparable to those of other antidepressant trials in late-life depression (Gottfries 1996). However, two studies have provided information on citalopram in this population; the first was a single-blind comparison between citalopram and nortriptyline (the latter at therapeutic plasma levels), and the second was a comparison of citalopram with placebo in depressed patients older than 75 years.

In the first study, 58 patients (mean age = 71 years) were randomly assigned to treatment with either citalopram at a dosage of 30-40 mg/day or nortriptyline at a therapeutic plasma level in a 12-week clinical trial (Navarro *et al.* 2001). The criterion for remission was a final Ham-D-17 score of 7 or less; the intent-to-treat remission rate was 69% for citalopram and 93% for nortriptyline. The remission rates for both medications were strikingly high in comparison with those in other trials; whether this result derived from differences in patient population or differences in study design is not obviously apparent.

The second trial is unique in the literature because it is the only study to focus on treatment of depression in the "old-old." In this study, 174 patients were randomly assigned to treatment with either citalopram 20-40 mg/day or placebo in an 8-week clinical trial (Roose *et al.* 2004). The population was 58% female, with a mean age of 80 years and a mean baseline Ham-D-24 score of 24. The intent-to-treat response rate (50% reduction from baseline Ham-D score) was 41% in the citalopram group and 39% in the placebo group. The sample was divided for secondary analyses into patients with "severe" and "not severe" depression, which were defined as being either above or below the mean Ham-D score, respectively. The "not severe" group had a baseline Ham-D score of 22 and included 47 patients randomly assigned to receive citalopram and 59 patients randomly assigned to receive placebo. In this group, the intent-to-treat remission rate (Ham-D score [?] 10) was 34% for citalopram and 41% for placebo. The "severe" patient group had a mean baseline Ham-D score of 28 and included 37 patients randomly assigned to receive citalopram and 31 patients randomly assigned to receive placebo. In this group, the intent-to-treat remission rate was 36% for citalopram and 19% for placebo. Thus, citalopram was significantly more effective than placebo in the "severe" patient population, but this difference resulted not from an increased efficacy of citalopram compared with "not severe" patients but rather from a decreased efficacy of placebo.

A third study--an 8-week randomized controlled trial--compared citalopram (flexible dosage of 10-20 mg/day) and venlafaxine (flexible dosage of 75-150 mg/day) in the treatment of late-life depression (Allard *et al.* 2004). The study included 151 patients (mean age = 73 years; 73% female) with a mean baseline Montgomery-Asberg Depression Rating Scale (MADRS) score of 27 +- 4. The response rates for venlafaxine versus citalopram were 75% and 73%, respectively, and the remission rates were 19% and 23%, respectively. The differences between the response rates and the remission rates were quite striking; it is unusual to see such a differential.

There are two randomized controlled trials of escitalopram in the treatment of late-life depression. In one study, 517 patients (mean age = 75 years; 75% female; mean baseline MADRS score = 28 +- 4) were randomly assigned to receive escitalopram (10 mg/day), fluoxetine (20 mg/day), or placebo. There was no significant difference in response rates

across the three treatment conditions (response rates: escitalopram 46%, fluoxetine 37%, and placebo 47%) (Kasper *et al.* 2005). In a separate 8-week randomized, placebo-controlled trial of escitalopram (*N* = 264 patients; mean age = 68), the study failed to find a statistically significant difference in the primary measure of depression outcome (Bose *et al.* 2008). The dropout rate was 19% for escitalopram and 26% for placebo.

Venlafaxine. Only one available study provides meaningful information about venlafaxine in a geriatric population (Schatzberg and Cantillon 2000). In this randomized controlled clinical trial, 204 patients (mean age = 71 years) were randomly assigned to treatment with venlafaxine (75-225 mg/day), fluoxetine (20-60 mg/day), or placebo. The intent-to-treat remission rate (Ham-D-24 score [?] 8) was 42% for venlafaxine, 29% for fluoxetine, and 38% for placebo (no statistically significant differences). Significantly more patients treated with venlafaxine (27%) and fluoxetine (19%) discontinued study participation because of side effects than did those given placebo (9%) ($P < 0.05$). Cardiovascular measures, including heart rate and measures of cardiac conduction (including pulse rate, QRS, and QTc intervals), were assessed, and neither medication induced a significant change compared with placebo in any of these measures.

Duloxetine. In the one randomized controlled trial of duloxetine for the treatment of late-life depression, 311 patients (mean baseline Ham-D score = 22) were randomly assigned in a 2-to-1 allocation favoring duloxetine (Raskin *et al.* 2007). The response and remission rates were significantly greater for duloxetine than for placebo (response rates: duloxetine 37%, placebo 27% [$P < 0.001$]; remission rates: duloxetine 19%, placebo 15% [$P = 0.002$]). However, as with many other trials of antidepressant medication for the treatment of late-life depression, the remission rates were distressingly low.

SSRI side effects and safety. As a group of medications, the SSRIs have the same side-effect profile in older individuals as in younger ones--specifically, gastrointestinal distress, agitation, insomnia, and sexual dysfunction. Discontinuation rates for SSRIs are not statistically different from the discontinuation rates reported for nortriptyline after a therapeutic plasma level had been achieved in the geriatric samples.

With respect to safety, the SSRIs offer a significant advantage over the TCAs. SSRIs are relatively benign in overdose (Barbey and Roose 1998) and do not have an effect on blood pressure, heart rate, cardiac conduction, or cardiac arrhythmias (Glassman *et al.* 2002; Roose *et al.* 1998). However, hyponatremia is a side effect that occurs primarily in older patients. This side effect has been illuminated in observational studies, and the results are variable (De Picker *et al.* 2014). A study using the Danish National Registry suggested that the frequency of hyponatremia was highest during the first 14 days following the initiation of treatment. One study reported that use of an SSRI (compared with no use) was associated with a fivefold increase in the rate of hospitalization for hyponatremia, although the absolute increase was only 1.3% (Gandhi *et al.* 2017). Although uncommon, a confusional state can result from hyponatremia, and this potential cause should be considered when a patient's mental status changes while taking an SSRI.

SSRIs, SNRIs, and risk of bleeding. Studies of SSRI treatment show that after weeks of SSRI administration there is a consistent and significant reduction in platelet serotonin content, which is in the range of 65%-90% of the level seen in controls (Maurer-Spurej *et al.* 2004) However, studying the consequences of this serotonin reduction for platelet activation, bleeding time, and clotting time is a complex undertaking that is highly sensitive to methodological factors. Perhaps as a result, the data reported from such studies are mixed, but in general it appears that reducing the serotonin content in platelets significantly decreases both platelet secretory response and platelet aggregation, leading to decrements in platelet plug formation (Hergovich *et al.* 2000; Tseng *et al.* 2010). As a rough approximation, the SSRIs can be considered to have an "anti-platelet" effect similar in magnitude to that of aspirin (Kotzailias *et al.* 2006)

Systematic, replicated research has revealed an association between SSRI treatment and risk of upper gastrointestinal (UGI) bleeding and intracerebral hemorrhage in older adults (Hackam and Mrkobrada 2012). Several studies examining the association between UGI bleeding and the use of SSRIs or SNRIs have observed increased relative risks (RRs) for UGI bleeding associated with medication use compared with nonuse. For example, patients treated with SSRI medication were 1.7 times more likely to experience UGI bleeding (95% CI = 1.4-2.0) compared with non-SSRI users (Dall *et al.* 2009). To further examine this association, a retrospective study obtained data (from a voluntary, fee-supported database) on all patients older than 18 years who had undergone major surgery between January 1, 2006, and December 31, 2008, at 375 U.S. hospitals (Auerbach *et al.* 2013). Among the 530,416 patients identified, 72,450 had received an SSRI in the perioperative period, as documented by the hospital pharmacy records. Patients receiving an SSRI had a greater risk of bleeding (OR = 1.9; 95% CI = 1.04-1.15; number needed to harm [NNH] = 424) and a higher mortality rate (adjusted OR = 1.20; 95% CI = 1.07-1.36; NNH = 839) than patients who were not receiving an SSRI. In addition, the 23,395 patients taking SNRI medication appeared to have the same outcomes as the SSRI-treated patients.

Other Agents With Antidepressant Effects

Mirtazapine. As previously discussed, in one randomized controlled comparator trial of mirtazapine versus paroxetine in a geriatric population, the intent-to-treat remission rate was 38% for the mirtazapine group and 28% for the paroxetine-treated patients (Schatzberg *et al.* 2002). In this study, the rate of discontinuation due to adverse events was similar in both groups: 33% for mirtazapine and 29% for paroxetine.

Bupropion. One randomized controlled comparator trial of bupropion versus paroxetine in late-life depression has been published, and this represents the only data available on bupropion in this population (Weihs *et al.* 2000). In this 6-week clinical trial, 100 patients (mean age = 70 years), with a mean baseline Ham-D-24 score of 27, were randomly assigned to treatment with either bupropion (100-300 mg/day) or paroxetine (10-40 mg/day). The rate of response (defined as a 50% reduction from baseline Ham-D score) in the intent-to-treat analysis was 71% in the bupropion group and 77% in the paroxetine group. Remission data were not reported. The discontinuation rate was 17% in the bupropion group and 15% in the paroxetine group.

A second study of bupropion in late-life depression randomly assigned 418 patients (mean age = 71 years) to a 10-week trial of placebo or active drug. The study failed to find a statistically significant difference in the primary measure of outcome, although some secondary measures favored drug over placebo. The dropout rate was not different between the two treatment groups (Hewett *et al.* 2010).

Quetiapine. In one study of quetiapine monotherapy in late-life MDD, 338 patients (mean age = 71 years) were randomly assigned to receive quetiapine (mean dose = 159 mg; range = 50-250 mg) or placebo in an 8-

week trial. Interestingly, reduction in depressive symptoms was significantly greater in the quetiapine group than in the placebo group, with a response rate of 64% (vs. 30% for the group receiving placebo) and a remission rate of 56% (vs. 23% of those receiving placebo). Not surprisingly, the most notable side effect was somnolence, with a dropout rate from side effects of 10% in the quetiapine group compared with 4% in the placebo group (Katila *et al.* 2013).

Duration of Treatment

The belief that patients with late-life depression take longer to respond than younger patients has led to the dictum that for older patients, the minimum duration necessary for an adequate antidepressant trial is 12 weeks. However, it is currently unclear whether all patients require a 12-week trial before they can be considered nonresponders, because data on this topic have been sparse and somewhat contradictory. For example, a patient who is very symptomatic at week 11 is unlikely to improve dramatically and meet remission criteria by week 12.

Two industry-sponsored 12-week randomized controlled trials of SSRIs in late-life depression comparing sertraline with nortriptyline and sertraline with fluoxetine both reported an increase in response rates at week 12 compared with week 8 (Bondareff *et al.* 2000; Newhouse *et al.* 2000). In the first study, 236 patients were randomly assigned to treatment with either fluoxetine or sertraline for 12 weeks. In the second study, 210 patients were randomly assigned to treatment with either sertraline or nortriptyline for 12 weeks. However, analyses of most 12-week antidepressant trials in late-life depression focused on time to response, and the early identification of nonresponders may be more useful to clinicians (Sackeim and Roose 2002).

Because patients who completed the two trials described above did not differ in demographic or clinical features, nor did the groups differ in rates of response or remission, the four groups were combined for the purpose of enhancing sample size with respect to other analyses (Sackeim and Roose 2002). For the total sample of completers ($N = 304$), the response rate was 69%. When the criterion for remission was a final Ham-D-24 score [?] 10, the remission rate was 59%. Although the median time to onset of sustained remission was 4 weeks, 36% of the patients required 8 weeks or longer to reach this point. However, if the remission criterion was a final Ham-D score [?] 6, then the time to sustained remission was 8 weeks, with 29% of the patients reaching the criterion only in week 12. Such findings are consistent with a view in which time to remission is dependent on the remission criteria. However, neither the overall response or remission rates nor the time to achieve sustained remission in this study supports the belief that patients with late-life depression are less responsive to antidepressant medication or take longer to respond (Sackeim and Roose 2002).

On the basis of these results, if a patient does not have at least a 30% improvement in the Ham-D score by week 2, they have only a 22% probability of being in remission at week 12 (using the remission criterion of a Ham-D score [?] 6). This probability progressively decreases, so that by week 6, if a patient does not have a 30% reduction in baseline Ham-D score, the probability of remission at the end of week 12 is only 7%. These results suggest that if there is not a moderate degree of symptomatic improvement early in treatment, clinicians can have a high level of accuracy in predicting that the patient will not adequately respond to this treatment within 12 weeks.

Therefore, the most important clinical implication of these data is that clinicians do not have to give a 12-week trial of antidepressant medication to all older depressed patients. Rather, they can make informed decisions about changing or continuing treatment at the 4-and 6-week time points based on the probability that given the patient's improvement to date, the remission criterion will or will not be met by week 12.

Augmentation of Antidepressant Treatment

If a trial of an antidepressant has failed, it is now common practice to try a second trial of monotherapy with a second antidepressant, often from a different class of medication, or to augment the antidepressant. There are data that support augmentation with aripiprazole, lithium, or methylphenidate.

A study of lithium augmentation in older patients compared response rates after 4 weeks in 145 younger (< 65 years) versus 22 older ([?] 65 years) patients with unipolar MDD. Although the older patients had a significantly higher response rate, the clinical utility of lithium in older adults could not be evaluated because there were no data on adverse events and side effects (Buspavanich *et al.* 2019).

Although stimulants are widely used in late-life depression, there is a paucity of data to support their use. In one notable study, 143 older adults with MDD (mean age = 70) were randomly assigned to receive 16 weeks of treatment with methylphenidate (mean dosage = 16 mg/day) plus placebo, citalopram (mean dosage = 32 mg/day) plus placebo, or a combination of both active medications. The decrease in Ham-D score was greater in the citalopram-methylphenidate group, as was the remission (Ham-D score < 6) rate (62%, compared with 42% in the citalopram-placebo group and 29% in the methylphenidate plus placebo group). Importantly, the three groups did not differ in number of side effects or dropout rate (Lavretsky *et al.* 2015).

A more recent strategy is the use of atypical antipsychotics to augment an antidepressant. One well-designed study compared the effectiveness of aripiprazole with placebo in older patients with MDD who did not respond to a trial of venlafaxine at a dosage of 150-300 mg/day for 12 weeks (Lenze *et al.* 2015). In the 181 of 468 participants (38% of the sample) who did not have their symptoms remit while taking venlafaxine, 91 were randomly assigned to receive augmentation with aripiprazole (2-15 mg/day) or placebo for 12 weeks. The researchers found a significantly greater remission rate in patients treated with aripiprazole (44%) compared with those given placebo (29%). The early discontinuation rate was 5% and did not differ between the treatment conditions. The most significant side effect was akathisia, which was observed in 27% of patients randomly assigned to receive aripiprazole vs 12% of those randomly assigned to receive placebo. However, the akathisia was reported as mild and did not persist.

Treatment-Resistant Depression in Older Adults

Treatment-resistant depression (TRD; two failed trials of antidepressants) in older adults is a leading cause of disability, excess mortality from suicide, and dementia. Although TRD in older adults is common, there are few data to guide more accessible pharmacological strategies other than intravenous ketamine and electroconvulsive therapy (ECT).

Intravenous ketamine, an anesthetic agent that blocks *N*-methyl-D-aspartate (NMDA) glutamate receptors, has substantial benefits for mood, quality of life, and reduced suicidality, and is fast and effective for TRD. Randomized controlled trials (using placebo or midazolam control) show that a 0.5-mg IV infusion given over 40 minutes provides a rapid antidepressant response, and its likelihood is undiminished by prior antidepressant failures (Coyle and Laws 2015). Meta-analyses have examined the antidepressant effect of intravenous ketamine, the largest of which included 21 studies and 437 TRD patients (Coyle and Laws 2015), finding a significant and rapid reduction of depressive symptoms after a single intravenous infusion of ketamine. However, the safety and efficacy of ketamine in older adults are poorly understood because such studies have excluded adults ages 65 years and older.

The available data on ketamine use in older individuals with TRD are from a case series of 53 patients (mean age = 67 years), who received four ketamine infusions over 2 weeks (Lipsitz *et al.* 2021). A response rate of 27% was reported (with response defined as > 50% reduction from the baseline Quick Inventory of Depressive Symptomatology [QIDS] score). However, perhaps the most revealing information from this series was the side effect and safety data. During ketamine infusions, 36 participants (69%) experienced treatment-emergent hypertension, which in general resolved after 20 minutes and was more frequent among patients with preexisting hypertension. Therefore, the management of blood pressure during ketamine infusion has emerged as the key safety issue for patients, particularly among those with baseline hypertension. Otherwise, the ketamine infusions were well tolerated, with the most frequent reported side effects being transient drowsiness, dizziness, and confusion.

The recent FDA approval of esketamine highlights the paucity of data on late-life TRD. There were two Phase III randomized placebo-controlled trials of esketamine nasal spray in patients age 65 years or older, which demonstrated acute and maintenance efficacy (Ochs-Ross *et al.* 2020).

However, a 4-week randomized, double-blind, placebo-controlled trial for TRD in patients age 65 years or older ($N = 138$) failed to show a statistically significant treatment difference between esketamine and placebo (weighted combination test two-sided $P = 0.06$) (Ochs-Ross *et al.* 2020). A planned subgroup analysis showed greater improvement in depression among participants in the esketamine group who were age 65-74 years and among those with an onset of depression before age 55 years. Fortunately, there were no serious adverse events reported. Overall, given the limited available data on efficacy and safety of intravenous ketamine and esketamine in late-life TRD, there is a compelling need for large, well-designed controlled trials.

The recent publication of the results of the OPTIMUM study offers a valuable guide for the evidence-based treatment of TRD (Lenze *et al.* 2023). This study enrolled 619 patients older than 60 years with TRD who were first randomly assigned (Step 1) to one of the following conditions for 10 weeks: 1) augment current antidepressant with aripiprazole (up to 15 mg/day), 2) augment current antidepressant with bupropion (up to 450 mg/day), or 3) switch current antidepressant to bupropion 450 mg/day. If the remission criterion of a MADRS score lower than 10 was not met after Step 1, patients entered Step 2 and were randomly assigned to receive lithium augmentation or nortriptyline adjusted to a therapeutic plasma level. Remission occurred in 28.9% of the aripiprazole augmentation group (risk ratio [RR] vs. the switch-to-bupropion group, 1.50; 95% CI, 1.06 to 2.13), 28.2% of the bupropion augmentation group (RR, 1.49; 95% CI, 1.04 to 2.12), and 19.3% of the switch-to-bupropion group (RR, 1.00 [reference]). Such remission rates were not only statistically significant but also clinically meaningful, given the low response rates typically seen in TRD. Interestingly, the rate of falls was highest in the bupropion augmentation group (0.55 falls per patient in bupropion augmentation, 0.33 falls per patient in aripiprazole augmentation, and 0.38 falls per patient in switch to bupropion) and included many injurious falls. In Step 2, there were no differences among groups in remission rates or falls. Remission occurred in 18.9% of patients in the lithium augmentation group and 21.5% in the switch-to-nortriptyline group. Overall, given the high rates of falls in the bupropion augmentation group, such results suggest that in this population with TRD, aripiprazole augmentation may be a better overall antidepressant strategy than either bupropion augmentation or a switch to bupropion (Lenze *et al.* 2023).

Antipsychotics in Older Adults

Neuropsychiatric symptoms are nearly ubiquitous in older adults with dementia, and about half of patients with Alzheimer's dementia develop agitation (Anatchkova *et al.* 2019). Antipsychotics and other psychotropic medications are used widely in the management of dementia-related psychosis or agitation because there are limited treatment alternatives; evidence for the effectiveness of nonpharmacological behavioral approaches is limited and may apply mainly to patients with mild behavioral symptoms.

The prevalence of dementia is approximately 2%-5% among adults older than 60 years, and antipsychotic use in neurocognitive disorders exceeds antipsychotic use in psychotic disorders due to the difference in disease prevalence rates (Colenda *et al.* 2002). Whereas the prevalence of schizophrenia in older adults remains below 1%, the prevalence of neurocognitive disorders increases to 15%-40% among adults older than 85 years (Thomas *et al.* 2001).

Special Safety Considerations in Older Patients

Antipsychotic Side Effects

Older patients can be more sensitive to the side effects of antipsychotics, which can include sedation, cardiac effects (e.g., tachycardia, orthostatic hypotension), anticholinergic side effects (e.g., dry mouth, blurred vision, constipation, urinary retention), cognitive effects, extrapyramidal symptoms, neuroleptic malignant syndrome, autonomic instability, and seizures.

Although most antipsychotics can cause orthostatic hypotension, it is most often observed with low-potency typical (conventional) antipsychotics such as chlorpromazine and thioridazine and atypical antipsychotics such as clozapine, risperidone, olanzapine, and quetiapine. Likewise, low-potency typical antipsychotics and clozapine have the greatest potential to cause anticholinergic effects. To varying degrees, the metabolic syndrome with glucose dysregulation is a potential side effect of all antipsychotic medications. Type 2 diabetes mellitus or diabetic ketoacidosis may be more common with clozapine and olanzapine compared with other antipsychotics, and blood glucose levels need to be monitored in elderly individuals (Jin *et al.* 2004). However,

one retrospective chart review in geriatric inpatients observed atypical antipsychotics to be generally weight neutral, suggesting that antipsychotic-induced weight gain may be more of a concern in younger adults than in older adults (Yeung *et al.* 2017).

The numbers of available dopamine neurons and dopaminergic receptors decrease with aging (Costa 2014), which may reduce the tolerance of elderly patients to antipsychotics, thus increasing the likelihood of neurological side effects such as extrapyramidal side effects (EPS) and tardive dyskinesia (TD). For example, Saltz *et al.* (1991) reported an incidence of TD of 31% after 43 weeks of typical antipsychotic treatment in a sample of elderly patients, and antipsychotic-induced TD is five to six times more prevalent in elderly individuals compared with younger ones (Jeste 2000). Atypical antipsychotics are more potent antagonists at the serotonin type 2A (5-HT$_{2A}$) receptor than at the dopamine D$_2$ receptor, resulting in fewer EPS and less TD compared with typical antipsychotics (Jeste *et al.* 1999). However, EPS emerging during risperidone use can be observed at much lower D$_2$ occupancies in older adults than in younger adults (33%-79% vs. > 80%) (Leon *et al.* 2010). Therefore, it has been proposed that neurological side effects may be more related to the absolute--as opposed to the relative (i.e., percentage)--number of occupied D$_2$ receptors. For this reason, the higher susceptibility of older patients to the neurological side effects of EPS and TD requires the use of dosages lower than those commonly used in young adults.

Sedation is one of the most common side effects of antipsychotic medications. Low-potency antipsychotics can be potent sleep inducers and have a greater propensity to cause anticholinergic side effects, which can lead to daytime confusion and disorientation in older persons. Antipsychotic use has also been associated with acute kidney injury in older adults, although the mechanism underlying this effect is not clear (Hwang *et al.* 2014). Lastly, there have been reports of an association between antipsychotic use and deep vein thrombosis in dementia, which may be related to the decrease in mobility and sedative effect of several antipsychotics (Parker *et al.* 2010).

Antipsychotic Effects on Cognition and Activities of Daily Living

All antipsychotic medications can have cognitive side effects, but the anticholinergic activity of antipsychotics may further compromise the already damaged central cholinergic projections in Alzheimer's disease. In parallel, sedation produced by antipsychotics may worsen the degree of disorientation and cognitive impairment in dementia. For example, among outpatients with Alzheimer's disease in the Clinical Antipsychotic Trials of Intervention Effectiveness-Alzheimer's Disease (CATIE-AD) trial, those who received atypical antipsychotics showed a greater decline in cognitive function, at a level consistent with 1 year's deterioration, in comparison with those who received placebo (Vigen *et al.* 2011). Such effects may be worsened by the use of antipsychotics with strong anticholinergic properties or by the addition of anticholinergic agents to treat drug-induced EPS. Therefore, if EPS develops following antipsychotic treatment in a patient with dementia, switching to an antipsychotic that is less likely to cause EPS is preferable to adding an anticholinergic medication to treat the EPS.

Antipsychotic Mortality Risks

The use of antipsychotics is associated with a dose-related increased risk of sudden cardiac death (Ray *et al.* 2009). Antipsychotic medications may block repolarizing potassium currents and prolong the QTc interval, which is associated with the development of torsades de pointes and sudden death (Goodnick *et al.* 2002). On the basis of a review of double-blind, placebo-controlled trials of atypical antipsychotics in patients with dementia, the FDA concluded that there was a significantly greater mortality risk (1.6-1.7 times) for patients treated with these medications compared with those receiving placebo, and that all antipsychotic medications must carry a black box warning to this effect (Jeste *et al.* 2008; Schneider *et al.* 2005). However, the absolute increased risk with short-term treatment is estimated to be relatively small (1%-2%).

There is no clear explanation as to why the use of antipsychotics is associated with an increased mortality risk specifically in patients with dementia. There may be a small increase in the risk of stroke for atypical antipsychotics (Brodaty *et al.* 2003), but the stroke risk is unlikely to be the sole factor leading to the increased mortality risk (Jeste *et al.* 2008). The increased risk of mortality may also be due to cardiac and metabolic side effects, hip fracture, cognitive worsening, falls, or pneumonia (Steinberg and Lyketsos 2012; Watt *et al.* 2020).

Studies comparing the mortality risk of various antipsychotics have not been conclusive. Whereas some analyses have observed increased incidence of cardiac arrhythmias and mortality among those taking typical antipsychotics, others have found no differences in outcomes between typical and atypical antipsychotics. In a large-scale medical records study involving more than 75,000 nursing home patients receiving antipsychotics, haloperidol was associated with the greatest increase in mortality risk, risperidone and olanzapine with an intermediate increase in risk, and quetiapine with the lowest increase in mortality risk (Huybrechts *et al.* 2012). Others have replicated this finding, with the caveat that some patients receiving higher dosages of haloperidol were being treated for delirium, which may have artificially increased the mortality rate observed because of the known association between delirium and increased mortality (Maust *et al.* 2015). Using Minimum Data Set-linked Medicare data, one recent analysis of older adults with depression and Parkinson's disease found that use of certain atypical antipsychotics (olanzapine, asenapine, brexpiprazole, iloperidone, lurasidone, paliperidone, and risperidone) compared with other atypical antipsychotics (aripiprazole, clozapine, or quetiapine) was associated with a higher all-cause mortality, which was mainly mediated by pneumonia (Chekani *et al.* 2020).

In summary, although there appears to be a dose-response relation in mortality risk in older adults, there is no clear evidence that establishes which type of antipsychotic is associated with the greatest risk of mortality. In addition, some studies suggest that the mortality risk in older adults may not be as large as has been believed, although this may be attributed to the decrease in antipsychotic prescribing among elderly patients with dementia with serious medical illness since the FDA black box warning was placed (Hulshof *et al.* 2015).

Antipsychotics in the Management of Behavioral Complications of Dementia

Patients with dementia often develop behavioral disturbances (e.g., agitation, aggression) or psychotic symptoms (e.g., delusions, hallucinations). As used here, the term *behavioral complications* denotes both behavioral disturbances and psychotic features.

Behavioral complications occur in most forms of dementia, lead to considerable burden for caregivers, and are common precipitants of institutionalization. Psychosis and behavioral dyscontrol often coexist in Alzheimer's disease, and treatment with antipsychotics is often prescribed for one or both sets of symptoms.

Personality changes occur early in dementia and include apathy, anhedonia, irritability, inability to pay attention, depression, and loss of emotional connection. In later stages, varying degrees of agitation may occur in more than half of Alzheimer's disease patients in outpatient clinics (Devanand *et al.* 1997) and nursing homes (Cohen-Mansfield *et al.* 1989). Other disinhibited behaviors include pacing, wandering, verbal and physical aggression, repetitive calling out, and screaming. While the prevalence of delusions in Alzheimer's disease varies widely in different samples, paranoid delusions of theft and suspicion are the most frequent types of delusions. Hallucinations, which can be visual or auditory, occur in 5%-15% of patients with dementia. In Alzheimer's disease, a typical hallucination is the conviction that someone else is in the house (i.e., phantom boarder syndrome).

In a series of 235 patients with Alzheimer's disease who were followed prospectively for up to 5 years, approximately half of the patients who manifested paranoid delusions or hallucinations at baseline were likely to manifest the same symptom 6 months later (Devanand *et al.* 1997). However, paranoid delusions or hallucinations were evident at three out of four consecutive visits (in only 10%-15% of patients), which raises the question of how long patients need to continue taking antipsychotics after treatment response.

Assessment of Psychopathology in Alzheimer's Disease

In elderly patients, assessment and treatment of psychopathology should occur after reversible medical conditions (e.g., urinary tract infection, metabolic abnormalities, iatrogenic or medication-induced symptoms) have been ruled out. Because of the impairment induced by many types of dementias, most rating scales have been developed as informant-based interviews. Commonly used rating scales for measurement of neuropsychiatric symptoms of Alzheimer's disease include the Neuropsychiatric Inventory (NPI; Cummings *et al.* 1994), the Neuropsychiatric Inventory--Nursing Home Version (Wood *et al.* 2000), the Behavioral Pathology in Alzheimer's Disease Rating Scale (BEHAVE-AD; Reisberg *et al.* 1987), the Consortium to Establish a Registry for Alzheimer's Disease (CERAD) Behavior Rating Scale (Tariot *et al.* 1995), and the Cohen-Mansfield Agitation Inventory (CMAI; Cohen-Mansfield *et al.* 1989). The NPI, which employs a quantitative time-efficient decision-tree approach, is the most widely used scale for evaluating the effects of antipsychotic treatment in individuals with dementia.

Neurobiological Mechanisms of Psychosis in Dementia

Although the precise pathophysiology underlying psychosis in Alzheimer's disease and other dementias is still unknown, neurobiological models have been proposed in recent years. For example, it has been suggested that alterations in dopaminergic, glutamatergic, serotonergic, and cholinergic neurotransmission may contribute to the development of psychosis in this population. 5-HT$_{2A}$ receptor polymorphisms have been significantly associated with the development of hallucinations and delusions in Alzheimer's disease (Nacmias *et al.* 2001; Tang *et al.* 2017). Specific genes, such as *ENPP6*, *SUMF1*, or the *APOE* e4 allele, have been identified as genomic correlates of psychosis in Alzheimer's disease (Ismail *et al.* 2022). In addition, cholinergic agents, including the acetylcholinesterase inhibitors (i.e., donepezil, rivastigmine, galantamine), can reduce neuropsychiatric symptoms in Alzheimer's disease and dementia with Lewy bodies, an effect that may implicate the cholinergic system in the development of psychosis in this population (Cummings *et al.* 2016). Neuroimaging studies have also implicated several brain regions in this process, including one analysis of 39 patients with Alzheimer's disease, which found that intensity of hallucinations was associated with atrophy and brain hypometabolism (on fluorodeoxyglucose-PET) in frontal regions and anterior insula, suggesting that dysfunction in brain regions important for cognitive control and attentional processes may be linked to the development of hallucinations (Blanc *et al.* 2014). Several studies have found that burden of neurofibrillary tangles (Ehrenberg *et al.* 2018) and hyperphosphorylated tau (Murray *et al.* 2014) is associated with extent and severity of neuropsychiatric symptoms in Alzheimer's disease. Finally, some studies have observed increased striatal dopamine (D$_2$/D$_3$) receptor availability among Alzheimer's patients with delusions (Reeves *et al.* 2009).

Overview of Psychotropic Medication Use in Dementia

Studies in the 1970s and early 1980s indicated that nearly half of inpatients with dementia in Veterans Administration hospitals (Prien *et al.* 1975) and in other settings (Michel and Kolakowska 1981) received psychotropic medications, primarily antipsychotics and benzodiazepines (Ray *et al.* 1980). Growing awareness of the neurological side effects of typical antipsychotics, particularly in dementia patients in nursing homes, led to the promulgation of the Omnibus Budget Reconciliation Act (OBRA) of 1987 (Elon and Pawlson 1992). OBRA required identification of target symptoms, justification for the use of antipsychotics, and mandatory attempts to decrease or stop the antipsychotic medication every 3 months. In 2012 the Centers for Medicare and Medicaid Services initiated the National Partnership to Improve Dementia Care in Nursing Homes and began to publicly report data on nursing home quality measures related to antipsychotic use. Nonetheless, antipsychotic medications are widely used and have remained the treatment of choice for behavioral complications in dementia.

Studies of Antipsychotics

In schizophrenia, antipsychotics are often assumed to be specific to the treatment of psychosis, much as improvement in behavioral dyscontrol is believed to be secondary to improvement in psychosis. While the literature is somewhat mixed, in patients with dementia, placebo-controlled studies have shown comparable advantages for antipsychotics over placebo for symptoms of both psychosis and behavioral dyscontrol. In placebo-controlled clinical trials with typical or atypical antipsychotics, response rates have varied between 45% and 60% for active medication and between 20% and 45% for placebo (De Deyn *et al.* 1999; Devanand *et al.* 1998; Street *et al.* 2000; Yury and Fisher 2007), with an overall advantage for antipsychotic over placebo in the range of 18%-26% (Kindermann *et al.* 2002; Ma *et al.* 2014).

Typical antipsychotics. Early placebo-controlled studies of typical antipsychotics used in the management of behavioral complications of dementia showed moderate efficacy with a high placebo response rate, but considerable EPS occurred even at moderate dosages (Finkel *et al.* 1995). No clear superiority has been noted for any particular typical antipsychotic in individuals with dementia. In a double-blind, placebo-controlled, randomized comparison of standard-dosage (2-3 mg/day) and low-dosage (0.50-0.75 mg/day) haloperidol in 71 outpatients with Alzheimer's disease, standard-dosage haloperidol was efficacious and superior to both low-dosage haloperidol and placebo for both psychosis and agitation (Devanand *et al.* 1998). However, EPS tended to be greater for haloperidol (2-3 mg/day) than for the other two conditions. These results suggest a relatively narrow therapeutic window for some typical antipsychotics in dementia patients who develop behavioral complications. If a typical antipsychotic is used, a starting dosage equivalent to haloperidol 0.5 mg/day is advisable, with subsequent titration to achieve an optimal trade-off between efficacy and side effects.

Atypical antipsychotics. Because of their more favorable safety profile, the atypical antipsychotics have gradually replaced typical antipsychotics in the treatment of behavioral complications in dementia. For example, incidence of TD is much lower with atypical antipsychotics than with the typical antipsychotic haloperidol (Jeste *et al.* 2000). In a study of 35 agitated patients with dementia who were switched from haloperidol to risperidone, the crossover was generally safe and effective (Lane *et al.* 2002). In addition, atypical antipsychotics can be safely administered with cholinesterase inhibitors (e.g., donepezil, rivastigmine, galantamine), which are used to treat the cognitive impairment of dementia (Weiser *et al.* 2002). The choice of atypical antipsychotic depends on the patient's clinical profile and the medication's side-effect profile.

Clozapine. Although clozapine can be more efficacious than other antipsychotics in schizophrenia and carries essentially no risk of TD, several side effects limit its use in patients with dementia and indicate that it should be reserved for those who do not respond to the other available antipsychotics. For example, clozapine causes substantial serotonergic blockade and can have antiadrenergic and antimuscarinic properties (Lieberman 1998). Sedation is common, seizure potential is elevated, and its anticholinergic properties can lead to dry mouth and constipation and can adversely affect cognition in elderly persons. In addition, circulating levels of clozapine rise with age and may be slightly higher in women than in men; sedation is common, and seizure potential is elevated (Centorrino *et al.* 1994; Kurz *et al.* 1998). Intensive monitoring is required for blood dyscrasias, particularly agranulocytosis, which is reported to occur in 0.38% of patients (Kane *et al.* 1988). These factors, as well as the increased risk of falls and fractures related to the side effect of orthostatic hypotension, limit the use of clozapine in older people. The few retrospective reviews and case reports available indicate moderate efficacy but significant adverse events in elderly patients with dementia (Chengappa *et al.* 1995; Pitner *et al.* 1995).

Risperidone. In young adults with schizophrenia, risperidone 6 mg/day has the best therapeutic profile compared with risperidone at lower and higher dosages (Chouinard *et al.* 1993). By contrast, the optimal risperidone dosage range is much lower for elderly persons (Katz *et al.* 1999). Compared with the other atypical antipsychotics, risperidone may be more likely to lead to EPS and TD, although its risk is still considerably lower than that associated with typical antipsychotics such as haloperidol;

in one study, risperidone's 1-year cumulative incidence of TD was a relatively low 2.6% in institutionalized patients with dementia (Jeste *et al.* 2000). Risperidone is mildly sedating and has the potential to cause orthostatic hypotension, although the latter effect is uncommon when low dosages are used in older individuals (Katz *et al.* 1999).

In a multicenter study, 625 nursing home patients with dementia who had behavioral complications were randomly assigned to receive risperidone--at 0.5 mg/day, 1 mg/day, or 2 mg/day--or placebo for 12 weeks (Katz *et al.* 1999). At study endpoint, response rates for risperidone 1 mg/day (45%) and 2 mg/day (50%) were significantly superior to rates for placebo and risperidone 0.5 mg/day, which showed similar response rates (33%). Patients receiving risperidone 2 mg/day were more likely than those receiving risperidone 0.5 mg/day or 1 mg/day to develop EPS and sedation, suggesting a relatively narrow therapeutic window. Therefore, a risperidone starting dosage of 0.5 mg/day in patients with dementia, with gradual upward dosage titration to 1-2 mg/day, is recommended. Its elimination half-life is between 20 and 22 hours, allowing for once-a-day dosing. Although a long-acting injectable risperidone preparation is available, this formulation has not been studied in the treatment of behavioral complications of dementia.

Olanzapine. Sedation and weight gain are prominent side effects of olanzapine, and its use has been associated with the development of metabolic syndrome. However, it has been suggested that atypical antipsychotic-induced weight gain may be more of a concern in younger adults than older adults (Atti *et al.* 2014; Yeung *et al.* 2017). Orthostatic hypotension is not common when low dosages of olanzapine are used in elderly patients (Street *et al.* 2000). Intramuscular olanzapine is a useful alternative to intramuscular haloperidol in the treatment of acutely psychotic, agitated patients with schizophrenia (Breier *et al.* 2002a) and may be a useful alternative to intramuscular lorazepam in patients with dementia (Meehan *et al.* 2002).

In a double-blind, placebo-controlled multicenter clinical trial, 206 nursing home patients with Alzheimer's disease and behavioral complications were randomly assigned to receive placebo or fixed-dosage olanzapine (5 mg/day, 10 mg/day, or 15 mg/day) for 6 weeks. Olanzapine 5 mg/day was significantly more efficacious than placebo, but olanzapine at the 10-mg/day and 15-mg/day dosages was not superior to placebo. Clinically, a starting dosage of 2.5 mg/day at bedtime with gradual upward titration to a target daily dosage of 5-10 mg is recommended.

Quetiapine. In a study of 284 elderly patients with dementia, quetiapine (average dosage = 96.9 mg/day) and haloperidol (average dosage = 1.9 mg/day) were indistinguishable from placebo on most measures of efficacy, although haloperidol led to more EPS (Tariot *et al.* 2006). Wide dosage ranges for quetiapine (from 12.5 to 800 mg/day) are used in clinical practice. Physicians often prescribe quetiapine because of its relatively benign side-effect profile and to take advantage of its main side effect, sedation, in patients who have insomnia. Although it has a short half-life (approximately 3-6 hours [Fulton and Goa 1997]), quetiapine's efficacy has been documented with twice-daily administration. Quetiapine may be started at 25 mg twice daily, with dosage increases as tolerated up to 300 mg twice daily, based solely on clinical response and side effects, because the optimal dosage range for quetiapine has not been identified.

Aripiprazole. In randomized placebo-controlled clinical trials, aripiprazole shows modest efficacy in the treatment of dementia-related psychosis and behavioral disturbances (De Deyn *et al.* 2013), although the literature has been mixed. One placebo-controlled study of aripiprazole in 208 outpatients with behavioral complications of Alzheimer's disease showed no advantage for aripiprazole on the main outcome measure (NPI score), but there was superiority on secondary outcome measures (Brief Psychiatric Rating Scale [BPRS] Psychosis and BPRS Core subscale scores). The average dosage used was 10 mg/day, which was generally well tolerated (De Deyn *et al.* 2005). The optimal dosage for aripiprazole is undetermined, but low starting dosages of 2-5 mg/day can be used.

Brexpiprazole. In May 2023, brexpiprazole was announced as the first FDA-approved treatment option for agitation associated with dementia due to Alzheimer's disease. The effectiveness of brexpiprazole for the treatment of agitation in Alzheimer's disease was determined in two 12-week randomized, double-blind, placebo-controlled, fixed-dose studies. Both found statistically significant and clinically meaningful improvements in key measures of agitation for brexpiprazole over placebo, with a favorable safety and tolerability profile. In the first study, 413 patients were randomly assigned to brexpiprazole 2 mg/day, brexpiprazole 1 mg/day, or placebo (Grossberg *et al.* 2020). Brexpiprazole 2 mg/day (but not brexpiprazole 1 mg/day) achieved significant and clinically meaningful improvement in total CMAI scores compared with placebo at week 12. In the second study, according to data released by the FDA (U.S. Food and Drug Administration 2023), 345 patients were randomly assigned to brexpiprazole 2 mg/day, brexpiprazole 3 mg/day, or placebo. Brexpiprazole 2 mg/day or 3 mg/day demonstrated significant improvements in total CMAI scores compared with placebo. Overall, the recommended starting dosage of brexpiprazole is 0.5 mg once daily on days 1-7, to increase up 1.0 mg daily on days 8-14, and increase to 2 mg daily on day 15. After 14 days, the dosage can be increased to the maximum recommended daily dosage of 3 mg daily, based on clinical response and tolerability. Main side effects include headache, dizziness, urinary tract infection, nasopharyngitis, and sleep disturbances (both somnolence and insomnia). It is worth noting that brexpiprazole still retains the black box warning of an increased risk of death among older patients with dementia-related psychosis.

Comparisons among antipsychotics. Overall, head-to-head comparison studies have shown few differences between typical antipsychotics in the treatment of behavioral complications in dementia (Carlyle *et al.* 1993; Petrie *et al.* 1982). In a study comparing a typical with an atypical antipsychotic, patients with dementia and behavioral complications were randomly assigned to receive flexible-dose risperidone, haloperidol, or placebo (De Deyn *et al.* 1999). In 344 patients, risperidone (mean dose = 1.1 mg/day), haloperidol (mean dose = 1.2 mg/day), and placebo produced no statistically significant differences in improvement rates or psychosis scores at week 12. In post hoc analyses, both haloperidol and risperidone were significantly better than placebo in reducing BEHAVE-AD total scores and CMAI aggression cluster scores, and risperidone was superior to haloperidol on the CMAI aggression cluster scores. However, patients taking haloperidol had significantly higher EPS scores at endpoint than did patients taking either risperidone or placebo, with no significant difference in EPS scores between patients receiving risperidone and those receiving placebo (De Deyn *et al.* 1999). Overall, risperidone's efficacy was comparable to that of haloperidol, but with a superior side-effect profile. In smaller studies in patients with dementia, comparisons of haloperidol and risperidone have yielded equivocal results (Chan *et al.* 2001; Suh *et al.* 2004).

In the 421 elderly patients who participated in the CATIE-AD, which compared risperidone, olanzapine, quetiapine, and placebo (first randomized phase), there were no significant differences in time to discontinuation because the superior efficacy of risperidone and olanzapine was compromised by their increased propensity for side effects; quetiapine was indistinguishable from placebo (Schneider *et al.* 2006). Consistent with these findings, a more recent systematic review found that risperidone, olanzapine, and aripiprazole had stronger data supporting their use in treating behavioral and psychological symptoms of dementia compared with quetiapine (Tampi *et al.* 2016). Therefore, efficacy must be weighed against side effects when prescribing such antipsychotics in a patient with dementia.

Comparisons of antipsychotics versus benzodiazepines. Despite the high prevalence of benzodiazepine use for the treatment of behavioral complications in dementia, there is limited evidence to support the use of benzodiazepines for this purpose. Early studies that compared antipsychotics with benzodiazepines suffered from methodological flaws, particularly in sample selection and study design (Burgio *et al.* 1992; Stotsky 1984). A more recent meta-analysis of 18 clinical trials found limited clinical efficacy of benzodiazepine use in Alzheimer's disease, but such evidence is limited by a dearth of high-quality, controlled clinical trials (Defrancesco *et al.* 2015). Unfortunately, benzodiazepines are known to have deleterious effects on cognition in older adults, both with and without cognitive impairment (Lee *et al.* 2018; Pomara *et al.* 1991, 2015), and their use can lead to tolerance and dependence. Therefore, benzodiazepines should be used at low dosages, and use should be restricted to short-term crisis management of agitated and anxious behaviors if antipsychotics or other medications are ineffective.

Studies of Other Agents

A small-sample study by Tariot *et al.* (1998) suggested that carbamazepine was effective in the treatment of behavioral complications of Alzheimer's disease, and there were suggestions that valproate was efficacious in a single-site study by the same research group (Porsteinsson *et al.* 2001). However, there is insufficient evidence to support the use of valproic acid for behavioral complications of dementia (Liu and Wang 2020). A recent large meta-analysis (N = 889,378) observed that among older adults with dementia (mean age [?] 80 years), anticonvulsants were associated with an odds of death eight times higher than that of placebo (Watt *et al.* 2020). Nonetheless, anticonvulsants such as valproate are routinely prescribed in nursing homes.

In a 12-week placebo-controlled trial in patients with dementia and agitation, the SSRI citalopram showed a small but significant advantage over placebo in some but not all measures of efficacy (Porsteinsson *et al.* 2014). However, the majority of patients received citalopram at a dosage of 30 mg/day, which is higher than the FDA dosage limit of 20 mg/day, which was instituted because of QT prolongation on the electrocardiogram at higher dosages.

In a recent Phase II randomized double-blind, placebo-controlled discontinuation trial of 217 individuals with dementia-related psychosis who had a response to pimavanserin,

patients were observed to have a significantly lower risk of relapse with continuation of the drug than with discontinuation at 26 weeks (Tariot *et al.* 2021). Only 79 patients completed the trial because it was stopped early for efficacy; therefore, larger trials are needed to determine the effects of pimavanserin on dementia-related psychosis.

Studies of other medications, such as buspirone (Santa Cruz *et al.* 2017), trazodone (Sultzer *et al.* 1997), lithium (Devanand *et al.* 2017), and propranolol (Shankle *et al.* 1995), have involved case series or small samples. These medications can be considered as therapeutic options only after antipsychotic treatment has failed.

Use of Concomitant Psychotropics

Use of anticholinergic agents to treat EPS should be avoided, particularly in Alzheimer's disease, in which a cholinergic deficit is believed to underlie much of the cognitive impairment. Trazodone at dosages of 25-200 mg/day can be used as a hypnotic in these patients. Benzodiazepine use should be limited to short-term crisis management of anxiety or agitation, and sedative-hypnotics such as zolpidem should generally also be avoided.

Optimal Duration of Antipsychotic Treatment

A trial of 6-12 weeks usually is sufficient to determine the outcome of an antipsychotic treatment trial. If the optimal antipsychotic dosage is reached quickly, clinical response may occur within the first 1-2 weeks. On the other hand, the need to adjust the dosage because of side effects may require a relatively prolonged trial period. However, conflicting evidence exists regarding how long antipsychotic medications should be continued. Whereas some reports indicate a moderate to high rate of relapse after discontinuation (Avorn *et al.* 1992; Hortwitz *et al.* 1995), others suggest that antipsychotics and other psychotropics can be discontinued in nursing home patients with dementia without increased risk of behavioral symptom relapse.

In a large randomized double-blind study examining relapse risk after antipsychotic discontinuation (Devanand *et al.* 2012), 180 Alzheimer's disease patients with psychosis or agitation/aggression received 16 weeks of open treatment with risperidone (mean dosage = 0.97 mg/day). Responders were randomly assigned to receive continuation risperidone for 32 weeks, risperidone for 16 weeks followed by placebo for 16 weeks, or placebo for 32 weeks. In the first 16 weeks after randomization, patients who discontinued to placebo showed greater rates of relapse than those who were assigned to receive continuation risperidone, for a relapse rate of 60% for placebo versus 32.9% for continuation risperidone. During the second 16 weeks, relapse rates were again greater with discontinuation to placebo compared with continuation risperidone, for a relapse rate of 48.1% for placebo versus 15.4% for risperidone. In a planned post hoc analysis, it was observed that participants with severe hallucinations at baseline had a threefold higher likelihood of relapse compared with mild or no hallucinations. Such results suggest that if an antipsychotic is discontinued in an individual with severe psychotic symptoms such as hallucinations, the individual should be monitored closely for symptom recurrence (Patel *et al.* 2017).

In contrast, results from the Halting Antipsychotic use in Long-Term care (HALT) study of 139 nursing home residents revealed successful and sustainable reduction of antipsychotic use without symptom recurrence (Brodaty *et al.* 2018). A "deprescribing" intervention was established in which practitioners, pharmacists, and nurses were educated on nonpharmacological techniques for behavioral and psychological symptoms in dementia. Over the 12-month study, the number of older adults on regular antipsychotics was reduced by 81.7% without an associated increase in behavioral or psychological symptoms.

Based on the findings of Devanand *et al.* (2012) described above, it can be argued that if a patient has shown a clear response to antipsychotic treatment, that patient should be continued on treatment for several months (up to 8 months) if side effects are not prominent. However, because of the adverse effects of antipsychotics in dementia, many suggest that a discontinuation trial should be considered for patients whose symptoms have been significantly improved or have been in remission for 3-6 months (Steinberg and Lyketsos 2012).

Treatment Monitoring of Target Behavioral Symptoms

The heterogeneous nature of behavioral complications suggests that specific target symptoms should be identified before antipsychotic treatment is initiated, and then monitored serially during the course of treatment with a scale such as the NPI. Cognition and activities of daily living need to be monitored, preferably with brief instruments such as the Mini-Mental State Exam. In patients who are being maintained on antipsychotics for extended periods, assessment for TD using the Abnormal Involuntary Movement Scale should be conducted at regular intervals.

Antipsychotics in Other Neurocognitive Disorders in Older Adults

The relative efficacy of antipsychotics in dementia related to neurocognitive disorders other than Alzheimer's disease has not been studied extensively, although antipsychotic treatment trials that have included patients with vascular dementia and other forms of dementia did not reveal any differences in treatment response between diagnostic subtypes (De Deyn *et al.* 1999; Katz *et al.* 1999). With the exceptions of dementia with Lewy bodies and Parkinson's disease, in which EPS are likely to worsen with antipsychotics, the recommendations for the use of antipsychotics in Alzheimer's disease generally apply to their use in other types of dementia (i.e., vascular dementia and frontotemporal dementia.)

Dementia with Lewy bodies is a subtype of dementia characterized by prominent EPS, fluctuating clinical course, hallucinations, and extreme sensitivity to the neurological side effects of antipsychotics (McKeith 2006). Patients with Parkinson's disease who take the carbidopa-levodopa combination (Sinemet) or dopamine agonists can develop iatrogenic psychosis from these medications. Lowering the dosage of the dopaminergic agent can lead to remission of psychotic symptoms, but the price paid may be an unacceptable increase in parkinsonian symptoms (Breier *et al.* 2002b). In such cases, antipsychotics with a very low propensity to cause EPS (e.g., atypical antipsychotics) can be considered, although the optimal choice of antipsychotic is an open question. Although some analyses have observed olanzapine to be safe and effective (Cummings *et al.* 2002), others have found no advantage for olanzapine over placebo in these patients (Breier *et al.* 2002b). Clozapine may be of some value in patients with Parkinson's disease (Friedman and Fernandez 2002), but the need for specialized monitoring limits its utilization. Quetiapine use is generally well tolerated in these patients (Fernandez *et al.* 2002), but its efficacy is unclear in dementia with Lewy bodies. Pimavanserin, a selective inverse agonist at the serotonin 5-HT$_{2A}$ receptor, was approved by the FDA in 2016 and has been shown to be efficacious in treating psychosis in Parkinson's disease (Cummings *et al.* 2014), although it can be cost-prohibitive compared with other existing antipsychotics.

In patients with delirium, short-term antipsychotic use is a standard treatment strategy in clinical practice. Several analyses have found antipsychotics to be helpful in lowering delirium severity (Breitbart *et al.* 2002), but recent literature has called this into question. For example, a recent systematic review of 5,607 adult inpatients with delirium found no significant differences in delirium outcomes between haloperidol, second-generation antipsychotics, and placebo (Nikooie *et al.* 2019). Likewise, a recent double-blind randomized controlled trial of ICU patients with delirium and acute respiratory failure found no differences in delirium duration between haloperidol, ziprasidone, and placebo (Girard *et al.* 2018).

Therefore, cautious use of antipsychotics can be considered when nonpharmacological interventions have failed and symptoms are severe or dangerous. The choice of antipsychotic is often based on side-effect profile, as haloperidol has a low risk of anticholinergic effects, whereas quetiapine is highly sedating but is less likely to cause EPS.

Antipsychotics in Late-Life Schizophrenia

Most older adults with schizophrenia were first diagnosed as young adults, but a minority of patients are first diagnosed with schizophrenia later in life. Although age at onset may affect clinical presentation, it does not appreciably influence the likelihood of response to antipsychotics or the occurrence of side effects (Sable and Jeste 2002).

In elderly patients with schizophrenia, a thorough evaluation followed by treatment with low dosages of atypical antipsychotics is the optimal strategy. In general, atypical antipsychotics appear to be at least as efficacious as and better tolerated than typical antipsychotics in this population. In older patients with schizophrenia, switching from typical antipsychotics to risperidone has been reported to be effective and well tolerated (Barak *et al.* 2002).

It has been difficult to conduct placebo-controlled trials in older patients with schizophrenia because tapering and stopping antipsychotic medications in schizophrenia is associated with a high risk of relapse. In a 4-month comparison trial of flexible-dose risperidone (n = 175) versus quetiapine (n = 553) in 728 mixed-age patients with a variety of psychotic disorders, quetiapine was as effective as risperidone and was less likely to require adjustment of concomitant antiparkinsonian medication. However, quetiapine was associated with more sedation, dry mouth, and dizziness (Mullen *et al.* 2001).

Open-label quetiapine (mean dose = 137.5 mg) was evaluated in a 53-week study of 184 elderly patients (mean age = 76.1 years), 72% with Alzheimer's disease and 28% with other psychoses (mainly schizophrenia), and was found to be effective for psychotic symptoms (Tariot *et al.* 2000). Importantly, new-onset TD did not develop in any patient over the 1-year period. Although this study was limited by the lack of placebo control or comparison with another antipsychotic to establish efficacy, the relatively benign side-effect profile of quetiapine is noteworthy. However, the CATIE studies in patients with Alzheimer's disease suggested that quetiapine's lack of efficacy compared

with olanzapine and risperidone (quetiapine did not separate from placebo) should be an equally important consideration (Schneider *et al.* 2006).

The effectiveness of long-acting injectable antipsychotics (LAIs) in older adults was evaluated in a naturalistic study of 1,168 older adults with schizophrenia after discharge from hospitalization (Lin *et al.* 2020). In this study, 151 participants received an LAI prior to discharge and 1,017 participants were taking oral antipsychotics at time of discharge. Over the 1-year study period, individuals on LAIs had a significantly lower rehospitalization rate (53.6% for LAIs vs. 66.1% for oral antipsychotics) and a longer time to rehospitalization (257 days for LAIs vs. 115 days for oral antipsychotics). Although the NNT for prevention of rehospitalization was 8, the clinical utility LAIs in older adults could not be fully evaluated because there were no data on adverse events.

Antipsychotics in Other Disorders in Older Adults

Low-dose quetiapine is commonly used off-label for the treatment of insomnia in older adults. However, the small number of available studies examining quetiapine for insomnia are restricted to younger, healthy subjects (Cohrs *et al.* 2004; Tassniyom *et al.* 2010), and robust studies on the safety and efficacy of quetiapine for insomnia in older adults are lacking. In addition, older adults can be particularly sensitive to the cardiac, anticholinergic, cognitive, metabolic, and neurological (e.g., EPS) side effects. In general, quetiapine use for the treatment of insomnia in older adults is to be avoided.

MDD with psychosis is an uncommon but clinically important diagnosis in older individuals. Based on studies in mixed-age samples, antipsychotics combined with antidepressants are the pharmacological treatments of choice, but ECT is still considered the most effective treatment for this disorder (Mulsant *et al.* 2001b; Sackeim *et al.* 1995). Expert consensus guidelines suggest that antipsychotic medication should be continued for 6 months following treatment response in MDD with psychosis in older adults (Alexopoulos *et al.* 2001). A double-blind trial of combination pharmacotherapy for MDD with psychosis showed that treatment with olanzapine plus sertraline was superior to treatment with olanzapine plus placebo in both older and younger adult patients, a finding that highlights the importance of combination antipsychotic and antidepressant treatment (Meyers *et al.* 2009).

Antipsychotics are used widely in the treatment of the manic phase of bipolar disorder across the life span (Levine *et al.* 2000). In bipolar disorder, there is ample evidence for the efficacy of typical and atypical antipsychotics, both individually and in combination with mood stabilizers (Sachs *et al.* 2002; Tohen *et al.* 2002). However, there is a surprising lack of data on the use of antipsychotics in geriatric patients with bipolar disorder. Because lithium's toxicity, particularly in the neurological domain, is problematic in older adults, anticonvulsants and atypical antipsychotics are most frequently used to treat mania in this population. However, in the absence of controlled data, the optimal choice of antipsychotic and the optimal dosage to use in these patients are open questions that need to be answered in future research.

Conclusion

Clearly, antipsychotic medications, particularly atypical antipsychotics, have an important role to play in the treatment of psychosis and behavioral dyscontrol in Alzheimer's

disease, other types of dementia, and other neurodegenerative conditions. Antipsychotics remain the first-line treatment for schizophrenia and other psychotic disorders across the life span. When antipsychotic medications are used in elderly patients, monitoring of target symptoms, somatic side effects, potential drug interactions, cognition, and activities of daily living is necessary. Likewise, antidepressant medications remain the mainstay pharmacological treatment for late life depression. However, antidepressant medications have specific risks in older patients that should be reviewed by clinicians prior to prescribing these medications, and a risk-benefit analysis should always be considered.

CHAPTER 62

Treatment of Women Excluding Pregnancy and Postpartum

Korrina A. Duffy, Ph.D.
Sarah Nagle-Yang, M.D.
C. Neill Epperson, M.D.

Reproductive-Related Events That Affect Psychiatric Disorders

Starting at puberty, females become more vulnerable to certain psychiatric disorders, a phenomenon that has been well documented (Bale and Epperson 2017). From menarche until menopause, females are approximately twice as likely as males to experience a major depressive disorder (MDD) episode (Bale and Epperson 2015), and the worldwide burden of disease due to MDD, as measured by disability-adjusted life years, is more than 1.5 times greater in females than in males (Cislaghi *et al.* 2020). Compared with males, females are at greater risk for panic disorder and onset of PTSD after exposure to an event that engenders a sense of helplessness, horror, or threat of death to self or others (Hantsoo and Epperson 2017). In addition to the greater burden of these disorders in females compared to males, the menstrual cycle, the perinatal period, and the menopause transition create unique psychiatric concerns. These periods of dynamic hormonal change are associated with increased risk for onset of mood disorders and cognitive changes, and these outcomes correlate with heightened distress (Bromberger and Epperson 2018; Epperson *et al.* 2013) and a decline in function (Epperson *et al.* 2015; Halbreich *et al.* 2003; Yang *et al.* 2008). Therefore, mood and cognitive complaints should be addressed by clinical providers who regularly treat women in their practice.

The aim of this chapter is to guide providers who prescribe neuroactive medications as pharmacotherapy specifically for postpubertal females experiencing psychiatric problems outside the perinatal period and common cognitive concerns in perimenopause and early postmenopause. The treatment of psychiatric illnesses during pregnancy and postpartum is covered in Chapter 63, "Psychopharmacology During Pregnancy and Lactation." Even though gonadal hormones have a broad impact on neurochemistry (McEwen and Parsons 1982), and sex differences have been observed in the pharmacokinetics (e.g., hepatic metabolism) of some psychotropic medications (Marazziti *et al.* 2013; Sramek *et al.* 2016), few studies have investigated whether sex affects the efficacy and tolerability of psychotropics (Duffy *et al.* 2020). Of those that have, the evidence generally does not suggest that pharmacotherapy for psychiatric problems should differ based on sex (except for those related to menstruation or menopause).

The first section of this chapter will indicate where sufficient evidence exists that would guide the prescriber to choose a class of medication or dosage differently for female versus male patients with the same disorder. The second section will recommend treatment options for menstrual cycle-related psychiatric concerns, focusing on treatment options for premenstrual dysphoric disorder (PMDD) and premenstrual exacerbation of psychiatric disorders. Because of the influences of sex hormones in these psychiatric concerns, drugs not typically considered in the context of psychopharmacology, such as steroid contraceptives and agonists or antagonists of the hypothalamic-pituitary-gonadal axis, that are effective in treating PMDD and premenstrual exacerbation will be described. The third section will consider treatment options for depression, psychosis, and cognitive complaints in perimenopausal and postmenopausal women as well as which psychotropics are safe to use in the context of chemical menopause. This section will also describe hormonal strategies as potential adjuncts to traditional psychopharmacology. In summary, this chapter focuses on the strength of the evidence for both psychotropic medications and other pharmacotherapies for psychiatric problems occurring in the context of hormonal changes outside the perinatal period and cognitive issues presenting during perimenopause and early postmenopause.

Sex Differences in the Safety and Efficacy of Psychotropic Medications

Antidepressants

Although the findings have been mixed, females may be more likely to respond to selective serotonin reuptake inhibitors (SSRIs) than males, whereas males may show a better response to serotonin-norepinephrine reuptake inhibitors (SNRIs) and the tricyclic antidepressant imipramine than females (Khan *et al.* 2005; Sramek *et al.* 2016). However, the magnitude of these differences may not be clinically significant, and SSRIs are still considered a first-line antidepressant for both sexes (Bayes and Parker 2018).

Antipsychotics

Although premenopausal females need lower dosages of antipsychotics to achieve efficacy, regardless of reproductive status, females are more likely to report side effects (Iversen *et al.* 2018; Lange *et al.* 2017; Seeman 2020). In a large naturalistic sample of patients taking antipsychotics for psychotic disorders, 13 side effects showed a sex difference, all of which were more frequently reported in females (Iversen *et al.* 2018) (Table 62-1). Females were also twice as likely as males to report the side-effect burden as being severe. To some extent, the greater side-effect burden may be explained by the fact that females are biologically more susceptible to certain adverse effects when taking antipsychotics. Not only does hyperprolactinemia occur more often in females (Melkersson *et al.* 2001), but high prolactin induced by antipsychotics reduces estrogen production, with unique effects in females (e.g., amenorrhea) (Iversen *et al.* 2018). Overall, females are more sensitive to antipsychotic-induced high prolactin and low estrogen, presenting with a host of symptoms driven by these hormonal changes, such as galactorrhea, infertility, hirsutism, sexual dysfunction, and decreased bone density (Iversen *et al.* 2018).

TABLE 62-1. Antipsychotic side effects reported more frequently in females than in males

* Concentration difficulties
* Sedation
* Accommodation disturbances (e.g., visual disturbances)
* Nausea
* Constipation
* Orthostatic dizziness
* Palpitations
* Pruritus
* Photosensitivity
* Increased pigmentation
* Weight loss
* Galactorrhea
* Headache

Source. Based on side effects reported in a large study of 834 patients with a psychotic disorder who were taking antipsychotics (Iversen *et al.* 2018).

Adjunctive estrogen treatment may be more effective in females than males (Begemann *et al.* 2012; Lange *et al.* 2017). A meta-analysis found that short-term estrogen treatment (for 2 to 8 weeks) was superior to placebo in augmenting the effect of antipsychotics, reducing total symptom severity and positive and negative symptoms in female patients with schizophrenia (Begemann *et al.* 2012). In a subanalysis of studies using estradiol products (either 17-b-estradiol or ethinyl estradiol), the effects were even stronger. In males with schizophrenia, estradiol valerate 2 mg/day (oral) treatment was not superior to placebo.

Because of safety concerns about long-term use of unopposed estrogens in women, combined oral contraceptives (COCs) are the first-line adjunctive therapy option for female patients of reproductive age whose symptoms are resistant to standard antipsychotic therapies (Begemann *et al.* 2012; Kulkarni *et al.* 2019). One review recommended use of COCs containing 17-b-estradiol, if possible, with at least 30 mcg of estrogen (Kulkarni *et al.* 2019). Despite promising case reports of adjunctive COCs improving psychosis (*N* = 2 [Coromina Sadurni *et al.* 2009; Felthous *et al.* 1980]), at least in the context of premenstrual exacerbation, no clinical trials have assessed the effect of COCs on symptom severity in women with schizophrenia. Importantly, the beneficial effects demonstrated in trials of estradiol cannot be extrapolated to formulations of combined estrogen and progestins, given that progestins could either increase or reduce the beneficial effect of estrogen. Despite the scarcity of randomized controlled trials (RCTs), COCs are nevertheless recommended because they are considered safe to use long-term, at least in studies in the general population (Hannaford 2000). Before starting the oral contraceptive pill, the psychiatric provider should confer with the patient's gynecologist.

Mood Stabilizers

For women needing a hormonal contraceptive agent and a mood stabilizer, drug interactions must be considered (Forrest *et al.* 2020). Hormonal contraceptive agents can interact with certain mood stabilizers, such as carbamazepine and oxcarbazepine, increasing clearance of hormones in COCs, transdermal patches, progestogen-only pills, and progestogen implants (Miller *et al.* 2015). Such interactions jeopardize the efficacy of the hormonal contraceptive in protecting women from unintended pregnancy. Some providers prescribe higher-dose contraceptives, but no research has been conducted to confirm the dosage that is needed to provide adequate contraception. Alternative birth control methods should be considered, including copper intrauterine devices (IUDs), levonorgestrel-releasing intrauterine systems, depot medroxyprogesterone acetate injections, and barrier methods. Similarly, estrogen-based contraceptives can compromise the efficacy of certain mood stabilizers (valproate and lamotrigine) by increasing their clearance and thereby lowering their circulating levels (Forrest *et al.* 2020). The progesterone-containing IUD is a highly reliable contraceptive with fewer effects on drug metabolism. Given the potential for valproate to increase the risk of fetal anomalies, reproductive-age women should avoid using it when possible. If valproate is necessary due to lack of efficacy of other mood stabilizing medications, a reliable method of birth control should be used.

Treating Menstrual Cycle-Related Psychiatric Concerns

Premenstrual Dysphoric Disorder

PMDD presents as a combination of emotional (e.g., depressed mood, anxiety, irritability, anger), behavioral (e.g., overeating, lethargy, insomnia), and physical (e.g., breast tenderness, weight gain) symptoms that cause significant distress and functional impairment (Epperson *et al.* 2012; Maharaj and Trevino 2015). This disorder is exceptionally common, with 1.8%-5.8% of menstruating women experiencing PMDD within a 12-month period (American Psychiatric Association 2013). The burden of this disorder is substantial: women with PMDD show impaired functioning across various domains (Halbreich *et al.* 2003; Yang *et al.* 2008) and are at a substantially higher risk for suicidal ideation, plans, and attempts (Osborn *et al.* 2021).

The diagnostic criteria in DSM-5 (American Psychiatric Association 2013) require that at least 5 out of 11 specific symptoms occur in most menstrual cycles, that symptoms present in the final week of the cycle, and that they improve within a few days of menses onset. A presumed diagnosis of PMDD must be confirmed with at least 2 months of prospective daily ratings of symptoms on a standardized daily questionnaire, such as the Daily Record of Severity of Problems (Endicott *et al.* 2006) or the Carolina Premenstrual Assessment Scoring System (Eisenlohr-Moul *et al.* 2017b). To make a PMDD diagnosis, it is critical to confirm that symptoms are isolated to the luteal phase and resolve within the first few days of menstruation. This differentiates PMDD from premenstrual exacerbation of an ongoing psychiatric illness, a topic discussed later in this section.

Although psychological symptoms are necessary for a PMDD diagnosis, the wide range of psychological, behavioral, and physical symptoms that occur in women with PMDD can make treating the disorder complex. Multiple pharmacological interventions may be needed to alleviate all burdensome symptoms. In addition, changes in terminology and diagnostic criteria have meant that samples of patients in research studies across the decades have been particularly heterogeneous. Because PMDD did not gain status as an official diagnosis until 2013, when DSM-5 was published, studies conducted before that often refer to participants as having premenstrual syndrome (PMS). Currently, PMS is used to describe menstrual-related mood or physical symptoms that interfere with daily life but do not meet criteria for a PMDD diagnosis. Before PMDD became an official diagnosis, however, many studies recruited women with a symptom severity and timing of onset consistent with DSM-5 criteria for PMDD even though they are referred to as having PMS. Recommendations for pharmacotherapies included in this section can be considered for those with severe PMS as well as PMDD.

Serotonin Reuptake Inhibitors

RCTs have consistently found that antidepressants with stronger serotonergic activity are superior in treating PMDD and mood symptoms of PMS than those with weaker serotonergic effects (Eriksson *et al.* 1995; Freeman *et al.* 1999; Pearlstein *et al.* 1997). As a result, the SSRIs sertraline

(50-150 mg/day), fluoxetine (10-20 mg/day), citalopram (10-30 mg/day), and escitalopram (10-20 mg/day) are considered the gold standard option for treating PMDD and severe PMS (Maharaj and Trevino 2015; Shah *et al.* 2008). Although paroxetine (12.5-25 mg/day) is an SSRI that effectively treats PMDD, it is nevertheless considered a second-line option for reproductive-age women because of concerns that it may increase the risk of congenital cardiac defects (Bar-Oz *et al.* 2007). The tricyclic antidepressant clomipramine (25-75 mg/day) and the SNRIs venlafaxine (50-200 mg/day) and duloxetine (60 mg/day) are also second-line treatment options (Maharaj and Trevino 2015). The SNRI venlafaxine is associated with worse discontinuation symptoms than SSRIs, and clomipramine has burdensome side effects, such as sedation, dry mouth, and weight gain (Sundblad *et al.* 1992, 1993). Except for duloxetine, which has been studied only with continuous dosing (Mazza *et al.* 2008; Ramos *et al.* 2009), all have demonstrated efficacy when dosed either continuously (administered daily throughout the entire menstrual cycle) or during the luteal phase only (administered in the 2 weeks before menses onset, also called intermittent dosing) (Maharaj and Trevino 2015).

Few studies provide evidence-based guidance for prescribers on whether to use luteal phase or continuous administration. A Cochrane Review of RCTs compared the efficacy of luteal phase dosing and continuous dosing of SSRIs in treating PMS and PMDD (Marjoribanks *et al.* 2013). These dosing regimens were found to be equally effective (Marjoribanks *et al.* 2013). Although this conclusion differed from that of a previous meta-analysis showing that continuous dosing was superior to luteal phase dosing (Shah *et al.* 2008), methodological differences account for this discrepancy. The methods of Marjoribanks *et al.* (2013) were stronger, leading to more convincing conclusions. Only a few studies have conducted a head-to-head comparison of these dosing regimens within the same study, but of those that have, luteal phase dosing was found to be at least as effective as continuous phase dosing (Freeman *et al.* 2004a; Landen *et al.* 2007; Steiner *et al.* 1997; Wikander *et al.* 1998; Wu *et al.* 2008). However, these dosing regimens may offer a trade-off in terms of efficacy (for alleviating certain symptoms) and tolerability (for inducing certain side effects). In an RCT, continuous dosing of paroxetine was more effective in treating some symptoms (e.g., depressed mood) but also increased the occurrence of an adverse effect (decreased libido) (Landen *et al.* 2007). In another study, overall side effects were more common in participants receiving continuous dosing than in those receiving luteal phase dosing, and in particular, headaches were reported more often when dosing was continuous (Steiner *et al.* 1997).

Another potential dosing regimen is symptom-onset dosing, in which medication is administered at the start of PMDD/PMS symptoms through the first few days of menstrual bleeding. Symptom-onset dosing has not been studied to the same extent as luteal phase and continuous dosing. In two RCTs, the efficacy of symptom-onset dosing was only modestly better than placebo (Yonkers *et al.* 2006, 2015), with another RCT suggesting that women with more severe PMDD may respond better to luteal phase dosing than to symptom-onset dosing (Freeman *et al.* 2005). At this time, symptom-onset dosing is not generally recommended, although it is not contraindicated if the patient is responsive to treatment and trying to limit side effects.

If symptoms are present at low levels during much of the follicular phase or symptom onset is unpredictable (e.g., if a woman has irregular menstrual cycles), then continuous administration is recommended. Furthermore, if physical symptoms are severe, some evidence suggests that continuous dosing may be more effective than luteal phase dosing (Marjoribanks *et al.* 2013). If symptoms are present during the luteal phase only and the onset of symptoms is predictable (e.g., if a woman has regular menstrual cycles), then luteal phase dosing could be an appropriate option, with the advantages of lower financial cost and fewer side effects (e.g., sexual dysfunction may be reduced). For some women, higher dosages of SSRIs are needed to adequately treat physical symptoms when luteal phase dosing is used (Cohen *et al.* 2002; Miner *et al.* 2002). Other treatment options include increasing the dosage during the luteal phase rather than using the same dosage throughout the cycle (called semi-intermittent dosing) or starting the medication only at the onset of symptoms (Steiner *et al.* 2006). Treating during the luteal phase only or at symptom onset is possible because the onset of action of SSRIs and other serotonin reuptake inhibitors (SRIs) is much more rapid when used for PMDD than when used for depression and anxiety disorders. In fact, one study found that the SSRI fluoxetine improved premenstrual symptoms on the second day of administration (Steinberg *et al.* 2012). Thus, deciding on a dosing regimen involves considering the predictability and duration of symptoms and weighing the potential improvement of specific symptoms against increased risk of side effects.

Combined Oral Contraceptives

Given that oral contraceptive pills replace fluctuating levels of endogenous ovarian steroids with more stable levels of exogenous hormones, they have been tested for their effectiveness in treating PMDD. A recent meta-analysis found that although COCs (estrogens plus progestins) are moderately effective at treating overall premenstrual symptoms, they are no more effective than placebo in treating premenstrual depressive symptoms (de Wit *et al.* 2021). Furthermore, even though the formulation of drospirenone (3 mg) combined with ethinyl estradiol (20 mcg) dosed as 24 days of hormone pills followed by 4 days of inactive pills (24/4 days) received FDA approval for the treatment of PMDD (U.S. Food and Drug Administration 2011) and is considered a second-line treatment option for PMDD and PMS (Maharaj and Trevino 2015), this formulation has not demonstrated superiority over other COCs in treating premenstrual depressive symptoms specifically (de Wit *et al.* 2021).

RCTs that have tested which regimen of drospirenone/ethinyl estradiol is most effective show mixed results. One randomized open-label study found that continuous dosing of drospirenone (3 mg) combined with ethinyl estradiol (20 mcg) for 168 days without a hormone-free interval was noninferior to the 24/4 day cyclical regimen (Machado *et al.* 2017). A double-blind, placebo-controlled RCT tested the efficacy of intermittent (21/7) versus continuous dosing of drospirenone (3 mg)/ethinyl estradiol (20 mcg) in treating premenstrual dysphoria but found neither regimen to be better than the other or superior to placebo (Eisenlohr-Moul *et al.* 2017a).

However, this finding contrasts with results from a double-blind, placebo-controlled RCT, which showed that drospirenone (3 mg)/ethinyl estradiol (30 mcg) in a 21/7 regimen reduced PMS severity compared with placebo (Shehata *et al.* 2020). Thus, currently, the most effective dosing schedule for drospirenone-containing COCs remains unknown until further investigation.

For women seeking treatment for overall premenstrual symptoms and not premenstrual depressive symptoms specifically, the formulation drospirenone (3 mg) combined with ethinyl estradiol (20 mcg) may be a good choice, especially if they are also seeking contraception. However, prescribing physicians should be aware that drospirenone-containing birth control pills may be associated with as much as a threefold higher risk for blood clots than products containing levonorgestrel or another type of progestin, but that the absolute risk of blood clots in women using COCs (overall) is still low (3 to 9 out of 10,000 per year) relative to the 1 to 5 women out of 10,000 each year who experience blood clots who are not taking COCs (U.S. Food and Drug Administration 2012).

Gonadotropin-Releasing Hormone Agonists

Gonadotropin-releasing hormone (GnRH) agonists reliably decrease ovarian hormone production (after a brief initial increase). This results in anovulation and amenorrhea, with GnRH agonists essentially creating a chemically induced menopausal state. Multiple studies show that GnRH agonists at dosages that suppress ovulation are effective in mitigating both physical and mood symptoms (Wyatt *et al.* 2004);

however, they are not considered a first-line option for PMDD or severe PMS because they create a hypogonadal state, inducing burdensome side effects (Maharaj and Trevino 2015). Besides having an unfavorable side-effect profile, they are also costly.

Three treatment options have been evaluated: leuprolide (3.75 mg intramuscular injection monthly), goserelin (3.6 mg subcutaneous injection monthly), and histrelin (one annual subcutaneous implant with 50 mg/implant). A meta-analysis of five RCTs testing the efficacy of treating PMS or PMDD with GnRH agonists found that both physical and mood symptoms improved more with GnRH agonists than with placebo (Wyatt *et al.* 2004). Although the effect was observably stronger for physical symptoms (e.g., breast tenderness, weight gain) than mood symptoms (e.g., depression, irritability), the difference was not statistically significant.

Treatment with GnRH agonists should be limited to 6 months unless add-back estrogen and progesterone are also administered. Otherwise, GnRH agonists can cause menopause-like side effects (e.g., decreased bone mineral density, hot flashes, night sweats) and masculinization (Maharaj and Trevino 2015). Although there is concern that add-back hormone therapy will lead to a resurgence of premenstrual symptoms, in the previously referenced meta-analysis, three studies that used add-back hormone therapy did not decrease the efficacy of GnRH agonists significantly (Wyatt *et al.* 2004).

One small randomized, double-blind crossover trial of patients receiving GnRH agonist monotherapy (leuprolide) tested different add-back hormone formulations to determine which was most beneficial in terms of mood effects (Segebladh *et al.* 2009). Three add-back combinations were studied: 1.5 mg gel estradiol/400 mg progesterone, 1.5 mg gel estradiol/placebo, and 0.5 mg gel estradiol/400 mg progesterone. The 1.5 mg gel estradiol/placebo combination was the best add-back option for patients with PMDD, as it was associated with lower irritability and depression compared with GnRH agonist monotherapy. However, estradiol-only treatment is not considered a safe option for women with an intact uterus because it can cause endometrial hyperplasia. The group that received 1.5 mg gel estradiol combined with progesterone had a resurgence of premenstrual symptoms that was more pronounced than in the group receiving 0.5 mg gel estradiol with progesterone. The 0.5 mg gel estradiol/progesterone group did not differ from the group receiving GnRH agonist monotherapy on measures of irritability, anxiety, depression, and impact on daily life but did report significantly more bloating. Overall, these findings are in line with previous research showing that when estradiol is combined with progestogens or natural progesterone, a higher dosage of estradiol causes more premenstrual symptoms than a lower dosage of estradiol (Bjorn *et al.* 2003).

Tibolone, a synthetic compound with estrogenic, androgenic, and progestogenic properties, has shown initial efficacy as a hormone therapy option in women with severe PMS who are using GnRH agonists. In a small RCT, tibolone outperformed placebo in reducing the number of hot flashes per day without exacerbating physical or psychological premenstrual symptoms (Di Carlo *et al.* 2001). Despite showing initial promise, in the past two decades since that RCT was published, no additional RCTs have followed up on these findings in women with PMS or PMDD. Although research supports the efficacy of various agents as add-back therapies, limited evidence precludes a strong recommendation of one type of add-back therapy over another (McLaren *et al.* 2012). Prescribers may need to try several add-back strategies to minimize resurgence of PMDD or PMS symptoms. Given the financial cost, menopause-like side effects, and lack of long-term safety data, prescribers should consider GnRH agonist treatment only for those with severe symptoms after SSRIs, SNRIs, and COCs have been given an adequate trial.

Serotonin Type 1A Receptor Agonist

Buspirone (10-40 mg/day), a partial serotonin type 1A receptor agonist, has shown efficacy in treating PMS and PMDD in two RCTs and is considered a second-line treatment option (Maharaj and Trevino 2015). A double-blind, placebo-controlled RCT tested the efficacy of luteal phase dosing versus continuous dosing of buspirone, ranging from 10 to 40 mg/day depending on response and tolerability (Landen *et al.* 2001). Although both dosing schedules observably improved all four mood symptoms (irritability, depressed mood, affect lability, and tension), only continuous dosing of buspirone was significantly more effective than placebo in treating irritability. A single-blind RCT compared buspirone 10 mg/day and fluoxetine 20 mg/day (both dosed continuously) in treating women diagnosed with PMS on the basis of changes in negative mood across three consecutive menstrual cycles (Nazari *et al.* 2013). Both medications demonstrated significant efficacy in the treatment of PMS, with neither showing superiority. Buspirone has a slow onset of action and has the unwanted side effects of sedation and cognitive and psychomotor impairment (Maharaj and Trevino 2015). In general, buspirone is well tolerated and may be a good alternative for patients who experience sexual dysfunction on SRIs. However, large double-blind, placebo-controlled trials are needed to investigate the efficacy, dosing, and side effects of buspirone further.

GABA Agonist

Alprazolam (0.25-0.75 mg/day), a benzodiazepine dosed from the luteal phase into menses, is not considered a first-line treatment for PMS or PMDD because of its lower efficacy rate compared with SSRIs (e.g., Diegoli *et al.* 1998) and the potential for benzodiazepine abuse (Maharaj and Trevino 2015). Six double-blind, placebo-controlled, randomized trials have been conducted (four crossover trials: Berger and Presser 1994; Harrison *et al.* 1990; Schmidt *et al.* 1993; Smith *et al.* 1987; two parallel-arm trials: Diegoli *et al.* 1998; Freeman *et al.* 1995). Although one study showed no benefit from alprazolam relative to placebo except for a statistically but not clinically significant improvement in depressive symptoms (Schmidt *et al.* 1993), in all other studies alprazolam was superior to placebo, improving a wide range of symptoms, including anxiety, irritability, tension, and depression (Berger and Presser 1994; Diegoli *et al.* 1998; Freeman *et al.* 1995; Harrison *et al.* 1990; Smith *et al.* 1987). However, alprazolam can induce sedation and impair cognitive and psychomotor functioning, particularly at higher dosages (Verster and Volkerts 2004). When the dosage was tapered with the onset of menses, no clinically significant withdrawal symptoms were observed (Freeman *et al.* 1995).

Dopamine Agonists

Luteal phase administration of the dopamine agonist bromocriptine (2.5-7.5 mg/day) was shown to decrease premenstrual mastalgia in women with

PMS (Elsner *et al.* 1980; Meden-Vrtovec and Vujic 1992; Ylostalo *et al.* 1982), perhaps because of its

prolactin-reducing properties. A review indicated that bromocriptine has inconsistent efficacy for other premenstrual symptoms (Halbreich *et al.* 2006). In a randomized, open-label trial comparing bromocriptine (dosed at 5 mg daily in the second half of the cycle) to cabergoline (dosed at 0.5 mg weekly in the second half of the cycle) (Aydin *et al.* 2010), cabergoline, a newer dopamine agonist, showed efficacy similar to that of bromocriptine in treating premenstrual mastalgia but fewer side effects such as nausea, vomiting, and headaches. Based on the current evidence, bromocriptine or the newer cabergoline may be helpful as an adjunct to first-line agents for women with PMDD who experience particularly bothersome mastalgia.

Aldosterone Antagonist

Luteal phase dosing of spironolactone (50-100 mg/day) is another strategy for treating bloating and mastalgia associated with PMDD and PMS (Maharaj and Trevino 2015). However, its effects on mood and other physical symptoms related to PMDD and PMS remain unclear, and findings are rather mixed (Halbreich *et al.* 2006). When treated with spironolactone, patients need to be monitored periodically for hyperkalemia.

Synthetic Hormones

Danazol is a synthetic androgen with some antiestrogen effects. At dosages greater than 200 mg/day, danazol suppresses ovulation, which drives its beneficial effects (Halbreich *et al.* 1991). Across multiple double-blind, placebo-controlled, randomized trials, danazol improves premenstrual mood and physical symptoms, particularly mastalgia (Deeny *et al.* 1991; Gilmore *et al.* 1985, 1989; Hahn *et al.* 1995; Kontostolis *et al.* 1997; Watts *et al.* 1987). However, its side effects include weight gain, hirsutism, acne, and decreased high-density lipoprotein cholesterol. One RCT tried dosing 200 mg/day of danazol in the luteal phase only (O'Brien and Abukhalil 1999). This regimen does not suppress ovulation, which is critical to the symptom relief of danazol (Halbreich *et al.* 1991), so although fewer side effects occurred, the only symptom alleviated was mastalgia (O'Brien and Abukhalil 1999). Overall, danazol is as efficacious as GnRH agonists but has more adverse effects and long-term risks (Halbreich *et al.* 2006), so its use in treating PMS and PMDD may be limited.

Summary: Treatment of Premenstrual Dysphoric Disorder

In summary, SSRIs have the best evidence for efficacy and are the first-line treatment for PMDD and premenstrual dysphoria in those with moderate to severe PMS. As with the treatment of other mood disorders, it is prudent to try several different serotonergic antidepressants, using continuous daily dosing if luteal dosing is not effective, before assuming that antidepressants are not effective for a given patient. Given the rapid onset of action of these drugs in the treatment of PMDD and PMS, a beneficial effect is expected in the first cycle. If the response is suboptimal, then a different dosage, regimen (e.g., luteal phase dosing or continuous dosing), or medication can be tried during the next menstrual cycle. However, approximately 40% of women with PMDD or PMS do not respond to SSRIs (Halbreich 2008), and SRIs are less effective for treating the physical symptoms of PMDD than the mood symptoms.

For those with PMDD or PMS who need contraception, there is evidence that some COCs can exacerbate PMDD and PMS mood symptoms even if they improve physical symptoms (Skovlund *et al.* 2016). If PMDD is suspected in a patient seeking contraception, it would be prudent to use either a drospirenone-containing COC or an IUD (at least to not exacerbate mood symptoms), although other methods are not contraindicated for women with PMDD or severe PMS. Psychiatrists and psychiatric nurse practitioners with little knowledge of contraception methods should collaborate with the patient's gynecologist or primary care provider. Drospirenone-containing COCs are effective in the treatment of overall premenstrual symptoms for patients with PMDD even though they are not more efficacious than placebo in treating depressive symptoms specifically.

For women with severe PMDD who are not sufficiently responsive to or cannot tolerate serotonergic antidepressants or drospirenone-containing COCs, GnRH agonist treatment should be considered, particularly for women with suicidal ideation or severe functional impairment. GnRH agonists can provide much-needed relief for these women while their providers determine an add-back strategy that does not exacerbate PMDD symptoms. GnRH therapy must be initiated in consultation and collaboration with the patient's gynecologist or primary care provider.

Premenstrual Exacerbation of Psychiatric Disorders

Premenstrual exacerbation (PME) is defined as premenstrual worsening of a preexisting psychiatric disorder (Hsiao *et al.* 2004) and is exceptionally common among women and girls with psychiatric disorders (58% of women and girls with a depressive disorder [Hartlage *et al.* 2004]; 44%-66% of women with bipolar disorder in prospective studies [Teatero *et al.* 2014]; 35%-45% of women with social anxiety disorder in a retrospective study [van Veen *et al.* 2009]; 20%-32% of women with psychotic disorders [Reilly *et al.* 2020]). Many women already taking psychotropic mediations still experience PME of their psychiatric symptoms (e.g., Hartlage *et al.* 2004), suggesting that their illness is not being adequately managed with current dosing regimens. For example, women taking antidepressants do not differ on the number of symptoms that become worse in the premenstrual phase compared to those not taking antidepressants (Hartlage *et al.* 2004). Even among women who appeared to be effectively treated with their current medication regimen (i.e., were not currently depressed based on semistructured diagnostic interviews), 44% nevertheless experienced PME of at least one symptom (Hartlage *et al.* 2004). In part, current dosing regimens, which typically involve a fixed dosage of medication across the menstrual cycle, may be inadequate because menstrual cycle hormonal changes affect the absorption, distribution, metabolism, and excretion of many drugs (Soldin *et al.* 2011). In fact, many small studies have shown that the blood levels of psychiatric mediations decrease substantially from the follicular phase to the luteal phase of the menstrual cycle despite constant dosages (e.g., Conrad and Hamilton 1986; Kimmel *et al.* 1992).

Despite the prevalence of PME, almost no clinical trials have tested which treatment options alleviate PME of psychiatric symptoms. Currently, treatment recommendations are extrapolated from case reports and treatment regimens used for PMS and PMDD (e.g., semi-intermittent dosing, in which medication dosage is increased during the luteal phase of the menstrual cycle) (Leahy 2017). The importance of considering PME among menstruating female patients cannot be overstated. Physicians who ignore the menstrual cycle risk simultaneously undertreating and overtreating their patients and potentially misinterpreting cycle-dependent symptoms as the medication being ineffective or causing side effects. Furthermore, many women who seek treatment for PMS or PMDD actually have PME of a psychiatric disorder. For example, as many as half of women seeking treatment for premenstrual disorders have PME of a depressive disorder (Plouffe *et al.* 1993). Therefore, careful consideration is needed regarding which symptoms occur at which phases of the menstrual cycle and whether women already on a psychiatric medication are experiencing breakthrough symptoms. Physicians should have women record daily premenstrual symptoms for at least 2 months to differentiate between PMDD and PME (Eisenlohr-Moul *et al.* 2017b; Endicott *et al.* 2006).

Major Depressive Disorder

Two small RCTs tested the efficacy of oral contraceptive pill (drospirenone/ethinyl estradiol) augmentation of antidepressants in preventing premenstrual breakthrough depression but found mixed results (Joffe *et al.* 2007; Peters *et al.* 2017). A pilot study of women who had persistent PME of depression on a constant dosage of sertraline were entered into a double-blind, placebo-controlled crossover trial to assess whether increasing the dosage of sertraline during the luteal phase worked better than increasing the dosage across the entire menstrual cycle (Miller *et* *al.* 2008). Semi-intermittent dosing resolved PME of depression, such that depression scores no longer differed in the luteal and follicular phases of the menstrual cycle, a difference that remained in the placebo group. This regimen has been used successfully in previous cases (Jensvold *et al.* 1992; Kimmel *et al.* 1992; Miller *et al.* 2002). Taken together, this evidence supports the use of dosage increases during the luteal phase rather than fixed dosage increases across the menstrual cycle.

Bipolar Disorder

According to a study following premenopausal women with bipolar disorder for 1 year, women with PME of bipolar disorder have greater overall symptom severity and increased risk of relapse in comparison with women with bipolar disorder without PME (Dias *et al.* 2011), demonstrating the need to adequately treat these women. Women with PME of bipolar disorder may benefit from variable dosing (Miller and Miller 2001). For example, in one case report, increasing the dosage of lithium for the week before expected menses onset was effective in reducing breakthrough affective psychosis symptoms in a patient with bipolar disorder mixed with psychotic features (Conrad and Hamilton 1986). Despite the importance of effectively managing bipolar disorder across the menstrual cycle, no treatment regimens for PME of bipolar disorder have been studied in clinical trials. Furthermore, distinguishing between bipolar disorder and PMDD or PMS is a diagnostic challenge with important implications, given that prescribing antidepressants to women with bipolar disorder can increase the risk of mania and hypomania (Miller and Miller 2001). In addition, bipolar disorder and PMDD are highly comorbid (Cirillo *et al.* 2012), so in the case of comorbidity, physicians need to be aware of the comorbid bipolar disorder in order to choose an appropriate treatment (Sepede *et al.* 2020).

Anxiety Disorders and Trauma-and Stressor-Related Disorders

Findings from prospective studies are mixed regarding the frequency of PME among women with an anxiety disorder or trauma-related disorder, such as PTSD (Nillni et al. 2021). One recent review concluded that there is not a universal at-risk menstrual cycle phase for women with an anxiety disorder or PTSD (Nillni *et al.* 2021). Thus, there are insufficient data to recommend changes in treatment regimen across the menstrual cycle due to PME of anxiety disorders or PTSD.

Schizophrenia

For PME of schizophrenia, physicians must decide on a case-by-case basis whether to raise antipsychotic dosages during the premenstrual phase, add hormone therapy (e.g., estrogens, estrogen/progesterone combinations), or target PMDD symptoms (Seeman 2012a). A case report found that two of four chronic inpatients with a diagnosis of schizophrenia or schizoaffective disorder showed improvement of their premenstrually exacerbated symptoms with daily oral conjugated estrogen (Premarin 0.625 mg) administered continuously for 3 months (Liao *et al.* 2002). A double-blind, placebo-controlled RCT in reproductive-age women with schizophrenia found that the addition of a 100-mcg estradiol transdermal patch produced significantly greater reductions in positive symptoms and general psychopathology symptoms relative to treatment with antipsychotic medication alone (Kulkarni *et al.* 2008). However, this study was not specific to women with PME, and more research is needed to determine which dosage, duration, and type of estrogen is most efficacious in treating premenstrual breakthrough symptoms.

Currently, treatment with estrogen remains controversial and has not been FDA approved for treating PME of schizophrenia (Seeman 2012a). However, low-dose birth control pills are a safe initial intervention for women with no contraindications (e.g., history of thromboembolic events). In a report of one patient with premenstrual psychosis, the oral contraceptive pill prevented the recurrence of psychotic symptoms in the premenstrual phase of the cycle (Coromina Sadurni *et al.* 2009). This may be because estrogen and progesterone administered orally interact with metabolizing enzymes and may boost blood levels of certain antipsychotics, which may be helpful for PME of psychotic symptoms (e.g., Chetty and Miller 2001; Gabbay *et al.* 2002).

Other treatment options include adding SSRIs if the premenstrually exacerbated symptoms are anxiety and depression or boosting the dosage of a prolactin-sparing antipsychotic for 3-5 days before menstruation if the exacerbated symptoms involve psychosis (Seeman 2012a). Case reports of women with PME of schizophrenia have indicated that adding the long-acting hormonal agent medroxyprogesterone acetate (Levitte 1997) or lithium (Glick and Stewart 1980) to antipsychotic treatment was efficacious when psychotic symptoms were exacerbated in the luteal phase of the cycle.

Summary: Treatment of Premenstrual Exacerbation of Psychiatric Disorders

In summary, PME of ongoing psychiatric disorders has been reported. However, few prospective RCTs have examined the effectiveness of pharmacological manipulations in treating breakthrough symptoms. Based on the current literature, it is reasonable to try increasing the antidepressant dosage during the luteal phase for women with confirmed PME of MDD. To manage PME in bipolar disorder or schizophrenia, luteal phase increase of a daily medication or addition of a new medication can be considered on a case-by-case basis with careful monitoring of the risks and benefits.

Treating Psychiatric Concerns in the Context of the Menopause Transition

The menopause transition is associated with fluctuating levels of ovarian hormones (e.g., estradiol) that can lead to a wide range of physical (e.g., vasomotor), behavioral (e.g., insomnia), and psychiatric (e.g., depression, anxiety) symptoms (Gordon *et al.* 2016, 2019), some of which may overlap with psychiatric disorders (Soares and Taylor 2007). For example, low energy, poor concentration, sleep problems, weight gain, and libido decreases are symptoms that occur in perimenopause and early postmenopause and in common psychiatric disorders, such as MDD (Soares and Taylor 2007). Selection of pharmacotherapy should consider whether a given medication is likely to exacerbate symptoms that co-occur with perimenopause and postmenopause (e.g., sexual dysfunction, weight gain) and whether it interacts with other drugs commonly used during the menopause transition, especially given the likelihood of concomitant use of other medications at this life stage (Maki *et al.* 2018).

Table 62-2 summarizes the reproductive phases as defined in the revised Stages of Reproductive Aging Workshop (STRAW+ 10) staging system (Harlow *et al.* 2012). Onset of vasomotor symptoms (VMS), depression, anxiety, and sleep and cognitive complaints can occur in perimenopause, when women may not be aware of menstrual irregularity yet (Gracia and Freeman 2018; Huang *et al.* 2018; Woods and Mitchell 2005). It is critical that mental health care providers familiarize themselves with this epidemiology because their patients are likely to report some, if not all, of these changes. Moreover, new onset of MDD is common during perimenopause (Cohen *et al.* 2006; Freeman *et al.* 2006), although MDD with perimenopause onset usually resolves within 2 years of the final menstrual period (Freeman *et al.* 2014). Therefore, treatment of new-onset MDD may not necessitate long-term therapy, although those who have a history of MDD before onset of the menopause transition may have ongoing concerns for years past the final menstrual period. Moreover, adverse childhood experiences increase the risk of new-onset MDD during perimenopause as well as the likelihood of experiencing MDD across the lifetime (Epperson *et al.* 2017). A prior history of MDD, a positive smoking history, and Black race are associated with earlier onset of menopause (Bromberger *et al.* 1997; Harlow *et al.* 2003; D. Zhu *et al.* 2018), and this should be considered when a woman presents with new-onset psychiatric concerns.

TABLE 62-2. Menstrual cycle characteristics of reproductive stages

Stage	Menstrual cycle characteristics

Stage	**Menstrual cycle characteristics**
Reproductive	
Early	Variable to regular
Peak	Regular
Late	Regular or subtle changes in flow heaviness or cycle length
Perimenopause	
Early	Increase or decrease in cycle length of [?] 7 days for at least one cycle in the past year
Late	Interval of amenorrhea ([?] 60 days)
Postmenopause	
--	Begins 12 months after the final menstrual period

Source. Based on the Revised Stages of Reproductive Aging Workshop (STRAW + 10) staging system for reproductive aging in women (Harlow *et al.* 2012).

Major Depressive Disorder

As described, perimenopause is a period of vulnerability for the development of depressive symptoms and major depressive episodes. Women with a history of depression were almost five times more likely to be diagnosed with MDD in the menopause transition than women without this history (Freeman *et al.* 2004b). In two longitudinal studies, premenopausal women with no prior history were two to four times more likely to report depressed mood in the menopausal transition compared to the premenopausal stage (Cohen *et al.* 2006; Freeman *et al.* 2006).

Dramatic changes in hormones during the menopause transition contribute to depression, as evidenced by research showing correlations between hormonal variability (in estradiol, follicle-stimulating hormone, and luteinizing hormone) and depressed mood (Freeman *et al.* 2004b, 2006; Ryan *et al.* 2009). Depression during perimenopause typically presents with classic depressive symptoms in combination with typical menopausal symptoms (e.g., VMS, sleep disturbance, weight changes, sexual concerns, and problems with memory and concentration) (Maki *et al.* 2018). As mentioned previously, menopausal symptoms often overlap with depressive symptoms (Soares and Taylor 2007), which can make diagnosing depression more challenging. This section draws extensively from the guidelines for treating perimenopausal depression published by experts from the North American Menopause Society (NAMS) and the Women and Mood Disorders Task Group of the National Network of Depression Centers (Maki *et al.* 2018, 2019). Psychiatrists and psychiatric nurse practitioners who regularly prescribe to midlife women may benefit from the Menopause Practitioner course offered by NAMS.

Antidepressants

Antidepressants are the first-line pharmacotherapy choice for treating perimenopausal and postmenopausal depression. Data on efficacy and tolerability support the use of SSRIs and SNRIs (Maki *et al.* 2018). However, only the SNRI desvenlafaxine has been tested specifically in perimenopausal and postmenopausal women with MDD in large, placebo-controlled RCTs (Clayton *et al.* 2013; Kornstein *et al.* 2010). In these RCTs, desvenlafaxine showed efficacy in both the perimenopausal and postmenopausal groups when dosed at 100-200 mg/day (Kornstein *et al.* 2010) and 50 mg/day (Clayton *et al.* 2013). At the recommended lower dosage of 50 mg/day, desvenlafaxine reduced depressive symptoms, alleviated pain intensity, and improved functioning (Clayton *et al.* 2013). Both studies showed that desvenlafaxine was well tolerated.

Although no other antidepressants have been investigated in large, placebo-controlled RCTs in a sample of well-defined perimenopausal or postmenopausal women with MDD, small, open-label studies support the efficacy of the SSRIs citalopram, escitalopram, fluoxetine, sertraline, and vortioxetine as well as the SNRIs venlafaxine, desvenlafaxine, and duloxetine in treating depression in this population (Maki *et al.* 2018, 2019).

Based on a pooled analysis of eight RCTs, women ages 50 and up had a 28% chance of remitting on an SSRI but a 48% chance on the SNRI venlafaxine (Thase *et al.* 2005), suggesting that venlafaxine may be more effective for perimenopausal and postmenopausal women (although menopausal status was not formally evaluated in the pooled analysis). This is in contrast to a large, double-blind RCT that did not find a significant difference in efficacy between the SNRI desvenlafaxine and the SSRI escitalopram in treating MDD in postmenopausal women (Soares *et al.* 2010) and a post hoc analysis of clinical trial data that did not find a difference in efficacy between SNRI venlafaxine and SSRIs in older women (Kornstein *et al.* 2014). In postmenopausal women, the remission rate in those taking venlafaxine versus fluoxetine was 52% versus 55% at the acute phase endpoint and 71% versus 63% at the continuation phase endpoint (Kornstein *et al.* 2014).

For perimenopausal women, bupropion (a norepinephrine-dopamine reuptake inhibitor) or vortioxetine (a serotonin modulator and stimulator) is sometimes prescribed because these medications are less likely than SSRIs and SNRIs to cause sexual dysfunction, weight gain, or sleepiness (Jacobsen *et al.* 2015; Schatzberg *et al.* 2014; Serretti and Chiesa 2009). To date, however, no double-blinded RCTs of bupropion or vortioxetine have been conducted in a well-defined sample of perimenopausal or postmenopausal women.

Of patients in the general population who try at least two successive trials of antidepressants at an adequate dosage and duration, a third of patients do remit (Rush *et al.* 2006). In selecting treatment for women experiencing a major depressive episode in the menopause transition, the prescriber should consider whether a patient has had an adequate response to a particular antidepressant in the past (as that should guide treatment selection), available data on efficacy and tolerability in perimenopausal and postmenopausal women, burdensome adverse effects (e.g., sexual dysfunction, weight changes), and safety (e.g., drug-drug interactions) (Maki *et al.* 2019). Although the side effects of SSRIs and SNRIs may exacerbate some menopause-related symptoms, many of these antidepressants improve other menopause-related complaints, such as VMS, sleep problems, and pain (Guthrie *et al.* 2018; Joffe *et al.* 2013, 2014; Maki *et al.* 2019). Paroxetine is the only antidepressant with FDA approval for treatment of VMS (Orleans *et al.* 2014); however, escitalopram, citalopram, venlafaxine, desvenlafaxine, and vortioxetine also have evidence to support effectiveness in this context (Freeman *et al.* 2017; Handley and Williams 2015; Santoro *et al.* 2015). Fluoxetine and sertraline may be less effective for VMS and so are considered second-line treatment options (Handley and Williams 2015). Practically, the efficacy of antidepressants in the treatment of VMS typically occurs at the lower end of the dosage range for treating depression, so titrating to a dosage that adequately treats depressive symptoms is likely to treat VMS as well.

Hormone Therapy

Although estrogen is ineffective in treating depression in postmenopausal women, it may be effective during perimenopause (Maki *et al.* 2018). In fact, four small studies, including two RCTs, have demonstrated that estradiol is effective in alleviating depressive disorders during perimenopause (Cohen *et al.* 2003; Rasgon *et al.* 2001; Schmidt *et al.* 2000; Soares *et al.* 2001). In addition, the effects on depression lasted even after a 4-week washout period, when VMS and night sweats had reemerged (Soares *et al.* 2001), suggesting that although VMS and sleep problems may affect risk for psychological distress (Joffe *et al.* 2009), they are not the underlying cause of the depression.

One RCT tested whether hormone therapy ((estradiol 0.1 mg/day via transdermal patch plus intermittent oral micronized progesterone 200 mg/day for 12 days every 3 months) given to euthymic perimenopausal or early postmenopausal women was effective at reducing the risk of developing depression (Gordon *et al.* 2018). It was particularly effective at preventing depression for women in early perimenopause. However, current evidence is not sufficient to recommend use of estrogen-based therapies for asymptomatic perimenopausal and postmenopausal women to prevent depression because the risks may not outweigh the benefits (Maki *et al.* 2019).

While it is common for perimenopausal women to be prescribed COCs to prevent unintended pregnancies, manage VMS, and preserve bone mineral density (Miller *et al.* 2018), there are no RCTs focusing on the use of combined estrogen plus progesterone for the treatment of depression in perimenopausal women (Maki *et al.* 2018). For women with depressive disorders, including MDD, COCs should be considered, particularly for early perimenopausal women with VMS because risk for unintended pregnancy is not inconsequential (Santoro 2016). However, antidepressant therapy should also be considered because there is no evidence that COCs will treat MDD in perimenopausal women.

Despite the profound impact of estradiol on serotonergic function (Bethea *et al.* 2002; Lasiuk and Hegadoren 2007; Shanmugan and Epperson 2014), study findings are mixed regarding whether estrogen administration augments or accelerates response to SSRIs in postmenopausal women with depression (reviewed in Maki *et al.* 2018). However, in a pooled analysis of eight RCTs, use of hormone therapy in postmenopausal women eliminated the difference in response rate to SSRIs otherwise observed between premenopausal and postmenopausal women (Thase *et al.* 2005). A small RCT found that conjugated equine estrogen augmented the effects of antidepressant medication in perimenopausal women with MDD (Morgan *et al.* 2005). Despite these promising findings, such therapies should be used with caution and preferably when other menopausal symptoms are also present, such as VMS.

Clinical practice guidelines from NAMS recommend restricting hormone therapy to the treatment of symptoms related to the hypogonadal state of menopause (Pinkerton *et al.* 2017). At present, hormone therapy has FDA approval for four indications: bothersome VMS, genitourinary symptoms, prevention of bone loss, and premature hypoestrogenism (Pinkerton *et al.* 2017). The recommendation for treatment is to administer the lowest effective dosage for the shortest duration possible. Currently, estrogen therapy is not FDA approved for the treatment of perimenopausal depression. Nevertheless, growing evidence in placebo-controlled trials indicates that it can be effective in alleviating depressive symptoms when prescribed for women who have experienced perimenopausal (but not postmenopausal) onset of depression. Numerous peer-reviewed publications support the hypothesis that a window of opportunity exists for the effective use of estrogen therapy in managing depressive symptoms during the menopause transition (Maki *et al.* 2019).

Summary: Treatment of Major Depressive Disorder in Perimenopause

Based on the evidence reviewed herein, women with a history of MDD during premenopause who experience a relapse in depression during perimenopause should be treated first with the psychopharmacology regimen that worked best in the past. If they have significant menopausal symptoms, such as hot flashes or night sweats, particularly if these lead to sleep disturbance, a provider may choose to add a COC or another hormonal intervention. Concerns about unintended pregnancy may lead the provider to choose a COC over transdermal estradiol. For those with an intact uterus, the use of a progestogen is critical. COCs certainly protect the uterine endometrium from hyperplasia; however, other forms and ways of taking progestins may have fewer adverse mood effects, particularly if the route of administration is an IUD or vaginally administered cream that passes hepatic metabolism.

For women with new onset of MDD during perimenopause, the evidence is sufficient to support consideration of estradiol as a primary treatment. If MDD resolves after 4-6 weeks of estradiol alone, progesterone should be administered to reduce the risk of endometrial hyperplasia. Close monitoring of mood is necessary because progesterone administration can worsen mood (Toffol *et al.* 2015). Regardless of reproductive stage and menopausal symptoms, however, the provider should take the severity of MDD into consideration and use pharmacotherapy that is FDA approved for the treatment of MDD when necessary.

Schizophrenia

In contrast to schizophrenia in men, which has a peak onset at age 21-25 years, schizophrenia in women has a first peak in onset at 25-30 years and a second peak during midlife, around the time of the menopause transition (Gogos *et al.* 2015; Hafner 2003; McGrath *et al.* 2008). It is thought that estrogen protects against psychosis, which is why, when estrogen levels fall with the onset of the menopause, women show a second period of susceptibility to developing psychotic symptoms or schizophrenia (Gonzalez-Rodriguez and Seeman 2018) or a worsening of symptoms for women with preexisting schizophrenia (Sajatovic *et al.* 2000, 2003).

Antipsychotics

After menopause, psychotic symptoms increase, which may warrant the use of higher dosages of antipsychotics (Crawford and DeLisi 2016; Gonzalez-Rodriguez and Seeman 2018). However, the incidence of side effects increases after menopause, and not only because menopausal women often need higher dosages (Barbui *et al.* 2005; Brzezinski *et al.* 2017; Seeman 2012b). Because female sex and advancing age increase susceptibility to QTc interval prolongation, postmenopausal women taking antipsychotics that can prolong the QTc interval should be monitored carefully (Seeman 2012b). Furthermore, cardiovascular risk should be monitored closely in this population given that antipsychotics, age, and estrogen loss all heighten vulnerability (Carr 2003). Furthermore, most antipsychotics induce hyperprolactinemia (Meaney and O'Keane 2007), which exacerbates the menopause-induced decline in estrogen (Gonzalez-Rodriguez and Seeman 2018).

The unfavorable shift in androgen-to-estrogen ratio can lead to acne, hirsutism, sexual dysfunction, and osteoporosis (Gonzalez-Rodriguez and Seeman 2018; Meaney and O'Keane 2007). It is recommended that physicians avoid prescribing antipsychotics that cause QTc interval prolongation, hyperprolactinemia, weight gain, and extrapyramidal symptoms (Gonzalez-Rodriguez and Seeman 2018); however, this leaves only partial dopamine agonist antipsychotics, which are problematic for many individuals with schizophrenia (Takase *et al.* 2015). To balance side effects and treatment efficacy, physicians should keep antipsychotic dosages as low as possible, avoid polypharmacy unless necessary, and try intramuscular depot injections if oral antipsychotics are ineffective (Seeman 2012b).

Hormone Therapy

Because of fluctuating gonadal hormones, augmenting antipsychotic medication with estrogen therapy may be helpful in perimenopause (Kulkarni *et al.* 2019). Based on evidence-based clinical practice guidelines, the first-line estrogen treatment is transdermal estradiol (50 or 100 mcg), plus progestin if the woman has a uterus (Kulkarni *et al.* 2019). Progestin should be micronized, such as natural progesterone products like Prometrium (100 mg oral or vaginal). However, if estrogen therapy is contraindicated (due to breast or uterine pathology), then raloxifene (120 mg/day oral) could be tried. Because of the risk of thromboembolism, women who smoke more than 20 cigarettes/day, are very sedentary, or are overweight should receive estrogen therapy with caution. Unfortunately, the high rates of smoking, obesity, and cardiovascular disease in women with schizophrenia (Hennekens *et al.* 2005) mean the use of hormone therapy is limited in this population.

It is not recommended that women start estrogen therapy after the age of 60 years, but it is acceptable to continue hormone therapy beyond this age if it was started in perimenopause and if appropriate safety monitoring is done (Sturdee *et al.* 2011). In women without a hysterectomy, estrogens must be combined with progesterone to prevent endometrial carcinoma.

Concerns about the adverse impacts of estrogen plus progestin treatment have led to the development of selective estrogen receptor modulators (SERMs), which may be a safer alternative to standard hormone therapy because these drugs can act as an estrogen agonist and antagonist depending on the target tissue (An 2016). Estrogen modulators as adjunctive treatment options hold therapeutic promise (Gonzalez-Rodriguez and Seeman 2018). Raloxifene, a second-generation SERM, is the only SERM currently FDA approved for long-term treatment and is approved for the treatment of osteoporosis (An 2016).

Adjunctive use of raloxifene, at least for some women, helps keep antipsychotic dosages low (Gonzalez-Rodriguez and Seeman 2018). Three recent meta-analyses of RCTs support the use of raloxifene as a safe and effective treatment option for postmenopausal women with schizophrenia (de Boer *et al.* 2018; Wang *et al.* 2018; X. M. Zhu *et al.* 2018). Raloxifene is effective in alleviating overall schizophrenia symptom severity and positive and negative symptoms; however, it is not effective in improving cognitive functioning and alleviating comorbid depression (de Boer *et al.* 2018). Raloxifene may be more efficacious for patients with less severe schizophrenia; however, more research is needed (Wang *et al.* 2018). Although raloxifene increases the risk for venous thromboembolic events (Ellis *et al.* 2015), the absolute risk is low, as exemplified by an increase of 1.2 women per 1,000 women annually in a study in which women with cardiovascular disease or multiple risk factors were given 60 mg/day of raloxifene (Barrett-Connor *et al.* 2006).

Summary: Treatment of Schizophrenia in Perimenopause

The higher dosages of antipsychotics often needed for menopausal women and the increase in susceptibility to adverse effects in older age can lead to a substantial side-effect burden in menopausal women with schizophrenia and have implications for

antipsychotic choice, dosing strategy, and hormone therapy consideration. Regardless of whether adjunctive hormone therapy is used alongside antipsychotics, menopausal women should be examined for side effects, screened regularly for cancer and osteoporosis, and monitored routinely for metabolic and cardiovascular markers (Gonzalez-Rodriguez and Seeman 2018). For older women taking estrogen-based therapy, the following physical health screening procedures are recommended: assessment of breast health (e.g., ultrasound + mammogram every 2 years after age 50 years, physical examination, family history, BRCA gene testing if indicated), full cardiac function (especially if the patient is taking clozapine), clotting profile on full blood examination, cholesterol levels, cancer markers (CA125), cervix smear test (in sexually active women), and thyroid, liver, and renal function tests (Kulkarni *et al.* 2019).

Treating Cognitive Complaints During the Menopause Transition

Cognitive decline is a common complaint during perimenopause and early postmenopause (Maki and Henderson 2016). In one large longitudinal study, immediate and delayed recall declined from the premenopausal to the postmenopausal stage (Epperson *et al.* 2013). Furthermore, women who had undergone surgical menopause experienced a faster decline of verbal memory, semantic memory, and processing speed (Georgakis *et al.* 2019). Although one longitudinal study indicated that while cognitive problems are evident during the menopause transition, cognitive function may return to premenopausal levels after menopause (Greendale *et al.* 2009), in a meta-analysis of four cross-sectional studies, phonemic verbal fluency and delayed verbal memory worsened from perimenopause to postmenopause (Weber *et al.* 2014).

One double-blind, placebo-controlled crossover study found that after taking the psychostimulant lisdexamfetamine 40-60 mg/day for 4 weeks, menopausal women with new-onset executive functioning (EF) complaints showed significantly greater improvement in subjective and objective measures of EF relative to women who received placebo (Epperson *et al.* 2015; Shanmugan *et al.* 2017). The difference between baseline and posttreatment assessments in the lisdexamfetamine group indicated a large effect size on a measure of self-reported EF, with a medium effect size for superiority of lisdexamfetamine over placebo (Epperson *et al.* 2015). The effect sizes for improved performance on the delayed paragraph recall task were small to medium.

A double-blind, placebo-controlled crossover study tested the efficacy of atomoxetine 80 mg/day, a selective norepinephrine reuptake inhibitor, in improving EF difficulties in healthy women who reported midlife onset of difficulties with memory, concentration, and attention (Epperson *et al.* 2011). Atomoxetine was superior to placebo in reducing subjective working memory complaints but did not differ from placebo on neuropsychological tests and behavioral assessments. The improvement from baseline in women taking atomoxetine indicated a medium to large effect size, although the effect size was small for the difference between atomoxetine and placebo.

Before trying psychostimulants, providers may consider prescribing vortioxetine, which has shown efficacy in treating cognitive problems in perimenopausal and early postmenopausal women in a small observational study (Freeman *et al.* 2017). Otherwise, providers may consider use of lisdexamfetamine for women with new-onset EF

difficulties in the menopause transition. Contraindications for psychostimulants should be considered in the overall evaluation, including symptomatic cardiovascular disease, hyperthyroidism, hypertension, active substance use disorder, or an active psychotic disorder (Greenhill *et al.* 2002). Because psychostimulants can increase blood pressure and heart rate, providers should monitor vital signs both at baseline and quarterly thereafter.

Avoiding Drug Interactions During Surgical and Chemical Menopause

Most antidepressants inhibit the metabolism of tamoxifen to its more active metabolites by the cytochrome P450 (CYP) 2D6 (CYP2D6) enzyme, reducing its anticancer effects (Desmarais and Looper 2009). A review provided clinical guidance on which antidepressants are safest to use with tamoxifen (Desmarais and Looper 2009). Paroxetine and fluoxetine have a strong effect on the metabolism of tamoxifen and should not be used. Bupropion may also affect tamoxifen metabolism, and therefore its use is not advised for women taking tamoxifen. Venlafaxine has little or no effect on tamoxifen metabolism and is considered the safest choice among the antidepressants. Desvenlafaxine is not metabolized by the CYP system and may be another safe option. Mirtazapine has not been studied extensively but seems to have minimal effect on CYP2D6. All other antidepressants inhibit CYP2D6 to some extent, with an effect size ranging from mild (e.g., citalopram, escitalopram) to moderate (e.g., sertraline, fluvoxamine, duloxetine).

Conclusion

This chapter reviewed the evidence that treating psychiatric problems in women requires consideration of hormonal changes and reproductive stage across the life span, not only during pregnancy and postpartum. Endogenous hormones can affect the effectiveness and tolerability of psychotropic medications, and, in turn, psychotropic medications can affect endogenous hormones. Therefore, when treating women, providers need to consider how the menstrual cycle affects psychiatric symptoms and how the menopause transition affects psychiatric as well as cognitive concerns and choose an appropriate treatment strategy with these reproductive events in mind.

CHAPTER 63

Psychopharmacology During Pregnancy and Lactation

D. Jeffrey Newport, M.D.
Teresa Lanza di Scalea, M.D., Ph.D.
Erin Richardson, M.S.N., R.N., A.P.R.N.
Tawny Smith, Pharm.D.
Nicole Scott, M.D.
Zachary N. Stowe, M.D.

Managing perinatal mental illness encompasses two concomitant health concerns (pregnancy and a psychiatric disorder) and must address the welfare of at least two patients (mother and child). Many nonpharmacological treatments are available for perinatal mental illness but are beyond the scope of the current chapter. Treatment options must be available, accessible, affordable, and effective for the illness, and in many cases this may involve pharmacotherapy. While definitive psychopharmacological treatment guidelines for perinatal illness remain elusive, there is a consensus that the principal clinical objective is to minimize infant exposure to the purported risks of both maternal mental illness and psychotropic medication. Reviews of the reproductive safety of psychotropic medications often provide cursory information about the impact of illness, rely on maternal report to address concomitant fetal exposures, and use extensive statistical interrogation that may not have meaningful clinical import. This chapter reviews the extant data regarding psychotropic reproductive safety and addresses how those data may be applied in clinical decision-making.

Maternal-Fetal Risk Assessment

Minimizing Infant Exposure

Management of any perinatal medical condition must address the reproductive safety of available therapies, the likelihood of illness recurrence without continued treatment, and the potential impact of untreated maternal illness. Minor ailments are routinely treated during pregnancy. Consequently, 90% of pregnant women take at least one medication, and over 50% take four or more medications (Ayad and Costantine 2015; Mitchell *et al.* 2011). Conversely, women with mental illness are often encouraged to discontinue psychotropic medication during pregnancy and lactation. Pregnancy is associated with high rates of antidepressant discontinuation (Petersen *et al.* 2011) and psychotropic nonadherence (Lupattelli *et al.* 2015).

Risks of Perinatal Mental Illness

Although the desire to avoid exposing the child to psychotropic medication is laudable, these decisions are often made with little awareness of risks attributable to maternal mental illness. Both the likelihood of perinatal recurrence or exacerbation and the evidence that the illness may be harmful to the child warrant attention.

A patient's likelihood of perinatal recurrence may be estimated by synthesizing prevalence data from epidemiological studies with evidence from the patient's own history. Patients with frequent episodes of psychiatric illness, a declining course, or a previous history of perinatal illness are more likely to become ill in the current puerperium. Studies of the course of maternal mental illness have found no evidence that pregnancy offers protection from relapse, and there is considerable evidence that the postpartum period entails heightened vulnerability. The incidence of depression during the perinatal period has been found to be comparable to the incidence of depression during nonperinatal periods (Buesching *et al.* 1986; Cutrona 1983; Kumar and Robson 1984; Manly *et al.* 1982; O'Hara *et al.* 1982; Watson *et al.* 1984). Two large studies, collectively comprising 122,400 women, found a 14%-20% incidence of prenatal major depressive disorder (MDD) (Marcus *et al.* 2003; Oberlander *et al.* 2006). In fact, 11% of women presenting for evaluation of postpartum depression reported symptom onset before delivery (Stowe *et al.* 2005). Discontinuation of treatment during pregnancy in women with histories of MDD or bipolar disorder increases the risk of episodes during pregnancy (L. S. Cohen *et al.* 2006; Newport *et al.* 2008c; Viguera *et al.* 2007b), although a recent meta-analysis indicated that among women with a history of MDD, only those with indicators of more severe depression (i.e., earlier age at onset, greater number of prior episodes, depression treated in a psychiatric rather than an obstetrical clinic) were at heightened risk for prenatal recurrence after antidepressant discontinuation (Bayrampour *et al.* 2020). Psychotic disorders may also worsen during pregnancy (Glaze *et al.* 1991; McNeil *et al.* 1984a, 1984b). The course of OCD appears to be variable during pregnancy, with 14%-33% of patients experiencing exacerbation (Guglielmi *et al.* 2014; Jenike *et al.* 1990; Williams and Koran 1997). Women with OCD who remained on pharmacotherapy throughout the perinatal period did not demonstrate a significant change in symptoms (House *et al.* 2016). Panic disorder during gestation has also been found to be variable, with 19% of patients experiencing

more frequent panic attacks and 30% experiencing less frequent attacks (Hertzberg and Wahlbeck 1999; Wisner *et al.* 1996a). Finally, obstetrical trauma and pregnancy loss can precipitate PTSD (Allen 1998; Engelhard *et al.* 2001; Fones 1996), with PTSD symptoms following stillbirth persisting into the next pregnancy (Turton *et al.* 2001).

Postpartum mental illness has been documented for millennia and is substantiated by modern research. Psychiatric hospitalization rates spike in the first postpartum month (Kendler *et al.* 1993), and up to 12.5% of all psychiatric admissions for women occur in the first postpartum year (Duffy 1983). Postpartum depression affects 10%-22% of adult mothers and up to 26% of adolescent mothers (Stowe and Nemeroff 1995; Troutman and Cutrona 1990). Women with bipolar disorder also face considerable postpartum risk (Kendell *et al.* 1987; Targum *et al.* 1979). Postpartum OCD may affect 9%-16% of new mothers (Miller *et al.* 2013; Zambaldi *et al.* 2009), with one-third of those experiencing de novo onset of OCD (Miller *et al.* 2013). Postpartum psychosis, the most severe postpartum syndrome, is thankfully rare, but its prevalence is 100 times higher among women with bipolar disorder (Brockington *et al.* 1982; Kendell *et al.* 1987).

The dangers posed by perinatal mental illness, for both mother and child, must also be considered. Maternal depression during pregnancy has been associated with slower fetal growth (Hedegaard *et al.* 1996; Schell 1981; Uguz *et al.* 2013), increased risk of preterm delivery and other obstetrical complications (Korebrits *et al.* 1998; Liu *et al.* 2016; Oberlander *et al.* 2006; Orr and Miller 1995; Perkin *et al.* 1993; Steer *et al.* 1992; Uguz *et al.* 2013; Venkatesh *et al.* 2016), and persistent cognitive, behavioral, and emotional problems in the child (Luoma *et al.* 2001, 2004; Meijer 1985; Nulman *et al.* 2002; O'Connor *et al.* 2003; Sondergaard *et al.* 2003; Stott 1973). Similarly, prenatal panic disorder is associated with preterm birth, low birthweight (Uguz *et al.* 2013), and gestational hypertension (Newport *et al.* 2016), and maternal anxiety is associated with higher rates of attentional problems in the child (Van den Bergh and Marcoen 2004). Depressed pregnant women are less compliant with prenatal vitamins and obstetrical care, receive poorer nutrition, and have greater use of prescription opioids, hypnotics, alcohol, tobacco, and illicit substances (Newport *et al.* 2012; Zuckerman *et al.* 1989). Finally, depressed pregnant women, and those with PTSD, often experience suicidal thoughts (Newport *et al.* 2007b; Smith *et al.* 2006) and may engage in suicidal behavior.

Postpartum depression also carries deleterious developmental consequences. As early as 3 months, infants of mothers with depression exhibit less facial expression, less head orientation, less crying, and more fussiness than infants of nondepressed mothers (Martinez *et al.* 1996). The children of depressed mothers manifest ineffective emotion regulation (Downey and Coyne 1990), delayed motor development (Galler *et al.*

2000), poor interpersonal interactions (Jameson *et al.* 1997), lower self-esteem (Downey and Coyne 1990), increased fear and anxiety (Lyons-Ruth *et al.* 2000), more aggression (Jameson *et al.* 1997), and more insecure and disorganized attachment behaviors (Martins and Gaffan 2000). Children of depressed mothers are ultimately more likely to experience emotional instability, to have behavioral problems, to exhibit suicidal behavior, and to need psychiatric treatment (Lyons-Ruth *et al.* 2000; Weissman *et al.* 1984).

Perinatal exacerbation of schizophrenia and other psychotic illnesses also warrants concern. Women with schizophrenia have a higher prevalence of substance abuse

during pregnancy (Miller and Finnerty 1996; Taylor *et al.* 2015) and may exhibit bizarre ideas about contraception, pregnancy, and child rearing that complicate their perinatal course (McEvoy *et al.* 1983; Riordan *et al.* 1999). Maternal schizophrenia has been associated with elevated rates of obstetrical complications (Bennedsen *et al.* 2001; Miller and Finnerty 1996) and perinatal death (Rieder *et al.* 1975).

The clinical data regarding the obstetrical and developmental consequences of maternal mental illness are supported by an extensive line of laboratory animal research. Preclinical studies across a variety of species indicate that stress during pregnancy and the early postpartum period adversely affects offspring growth, learning ability, and postnatal development, producing a range of biobehavioral aberrations that may persist into adulthood (for a review, see Newport *et al.* 2002).

Risks of Perinatal Psychotropic Exposure

The risks of psychotropic exposure may be broadly classified as acute or developmental adverse effects (Table 63-1). Acute effects (e.g., drug toxicity and withdrawal) are typically evident immediately and are not dependent on the developmental window of exposure. Developmental effects, by definition, are dependent on the developmental window of exposure and are often not evident until later. These include somatic teratogenesis (i.e., major and minor malformations) and neurobehavioral teratogenesis (i.e., alterations in brain development that affect the child's subsequent behavior, cognitive abilities, and emotional regulation). The window of vulnerability to somatic teratogenesis is limited to the embryonic phase of development; however, the fetus and breastfeeding infant are theoretically vulnerable to neurobehavioral teratogenesis.

TABLE 63-1. Potential risks of perinatal medication exposure

	Acute	**Developmental**
Pregnancy	Neonatal toxicity Neonatal withdrawal Drug-drug interactions	Somatic teratogenesis Neurobehavioral teratogenesis
Lactation	Infant toxicity Drug-drug interactions	Neurobehavioral teratogenesis

Psychotropic treatment during pregnancy and lactation has complicated clinical, ethical, and potentially legal consequences. Although reproductive safety data address such concerns, methodological shortcomings in some studies undermine the reliability of these data. Most glaring are the frequent lack of appropriate control groups and an overreliance on retrospective data collection--deficiencies demonstrated to introduce biases that potentially lead to overestimation of the impact of psychotropic exposure (Newport *et al.* 2008a). In particular, many studies rely on control groups of healthy volunteers, eliminating any opportunity to disentangle treatment from illness effects (McDonagh *et al.* 2014). Despite these limitations, ethical considerations preclude implementation of randomized clinical trials to evaluate the reproductive safety of psychotropics. The reproductive safety database for psychotropics thus consists of a diverse conglomeration of observational studies, case reports, case series by pharmaceutical companies and academic centers, birth registries, retrospective surveys, reports from teratology or poison control centers, clinical and preclinical pharmacokinetic investigations, review articles summarizing data from these sources, and medication safety rating systems.

FDA Pregnancy and Lactation Labeling Rule

The FDA's new Pregnancy and Lactation Labeling Rule (PLLR) was launched in 2015 with a plan for staggered implementation over the following 3-5 years. The PLLR replaced the long-standing pregnancy letter category with the following information: pregnancy exposure registration, narrative risk summary, clinical considerations, and data description of supporting evidence. In addition to pregnancy and lactation profiles, the PLLR also summarizes evidence for "males and females of reproductive potential." The PLLR is subject to ongoing updates as evidence emerges but is required only for medications receiving FDA approval after June 30, 2001.

Antidepressants

The use of antidepressant medications in pregnancy has been extensively reviewed (McDonagh *et al.* 2014; Yonkers *et al.* 2014), and multiple meta-analyses have found no association between antidepressant use in pregnancy by women with psychiatric illness and the risk for major malformations (T. R. Einarson and Einarson 2005; Gao *et al.* 2018; Grigoriadis *et al.* 2013). Overviews of the individual categories of antidepressants are included below.

Selective Serotonin Reuptake Inhibitors

Reproductive safety data on the selective serotonin reuptake inhibitors (SSRIs) have rapidly accrued in recent decades. Meta-analyses investigating SSRIs found no overall association with birth defects among infants of women with psychiatric illness (Gao *et al.* 2018; Reefhuis *et al.* 2015). Despite overall reassuring data, some concerns with specific SSRIs have emerged. Reefhuis *et al.* (2015) found an increased risk of anencephaly, atrial septal defects, right ventricular outflow tract obstruction, gastroschisis, and omphalocele with paroxetine exposure and an increased risk of right ventricular outflow track obstruction defects and craniosynostosis with fluoxetine. A meta-analysis of fluoxetine outcomes also reported an association (OR = 1.36) with cardiovascular malformations (Gao *et al.* 2017). Analysis of a managed care database revealed a higher odds ratio for cardiovascular malformations with exposure to paroxetine compared with other antidepressants (GlaxoSmithKline 2005). Three large case-control studies (Alwan *et al.* 2007; Berard *et al.* 2007; Louik *et al.* 2007) have produced largely reassuring results, though with some concerns. The first (Alwan *et al.* 2007) reported small increases in the risk for three uncommon malformations: anencephaly (OR = 2.4), craniosynostosis (OR = 2.5), and omphalocele (OR = 2.8). The second study (Louik *et al.* 2007) reported an increased risk for omphalocele (OR = 5.7) and septal defects (OR = 2.0) with sertraline exposure and for right ventricular outflow tract obstruction defects (OR = 3.3) with paroxetine exposure. The third study (Berard *et al.* 2007) found no evidence of increased risk for cardiovascular or other malformations with SSRI use, unless women were taking more than 25 mg of paroxetine per day, in which case an increased risk for cardiovascular (OR = 3.1) and overall malformations (OR = 2.2) was observed. Using the Medicaid Analytic eXtract database, Huybrechts *et al.* (2014a) found an overall adjusted risk of 1.06 (95% CI, 0.93-1.22) for any cardiac defect with the use of SSRIs in the first trimester, a risk of 1.07 (95% CI, 0.59-1.93) for right ventricular outflow tract obstruction with the use of paroxetine, and a risk of 1.04 (95% CI, 0.76-4.41) for ventricular septal defects with the use of sertraline.

A handful of studies have systematically assessed child development after prenatal exposure to antidepressants. Two studies (Nulman *et al.* 1997, 2002) assessed children (ages 15-86 months) who had been prenatally exposed to fluoxetine (*n* = 90) or tricyclic antidepressants (TCAs) (*n* = 126), collectively comparing them with nonexposed children (*n* = 120). No differences were observed with respect to global cognitive, psychomotor, or language development. The same group compared children who had been exposed to SSRIs in utero with children born to mothers without depression and found no differences in IQ or behavior (Nulman *et al.* 2012). A similar study that compared children (ages 6-40 months) with prenatal SSRI exposure (*n* = 31) and children without antidepressant exposure (*n* = 13) observed no differences in global cognition but reported lower psychomotor scores for the SSRI-exposed children (Casper *et al.* 2003). Unfortunately, limitations of these studies render their implications speculative at best. Children were not age-matched in any of these studies, and the predictive validity of these indices across child developmental stages has not been established (Black and Matula 2000). In addition, the Casper *et al.* (2003) study was confounded by the fact that 29% of the participants were enrolled after delivery, which could result in an overrepresentation of children with developmental abnormalities. A study of 69 (46 SSRI exposed, 23 nonexposed) children that eliminated the age confound by examining the children at two fixed time points--2 months and 8 months of age--reported no differences between the exposed and nonexposed children in cognitive or motor development (Oberlander *et al.* 2004). Finally, an assessment of 4-year-old children found no evidence that prenatal SSRI exposure affected externalizing or attentional behaviors (Oberlander *et al.* 2007). It is noteworthy that several of these developmental studies involved a significant overlap between cohorts of children, thereby limiting further the cumulative sample size of extant follow-up studies.

A rapidly emerging literature including 14 studies within 10 years has explored whether there is an association between prenatal antidepressant use and autism spectrum disorders in offspring. At first glance, the results appear to be decidedly mixed; however, closer inspection reveals evidence of an ascertainment bias due to ethnic disparities in access to health care among studies using a population-based control group (Vega *et al.* 2020). Studies overcoming this source of bias by using a discordant sibling comparison group demonstrated no connection between fetal antidepressant exposure and subsequent diagnosis of autism (OR = 0.85).

Data regarding the impact of prenatal antidepressant exposure on rates of miscarriage, preterm delivery, and low birthweight are decidedly mixed. Some investigators have reported an association with such outcomes (Chambers *et al.* 1996; Chang *et al.* 2020; Chun-Fai-Chan *et al.* 2005; Eke *et al.* 2016; Oberlander *et al.* 2006; Pastuszak *et al.* 1993; Ross *et al.* 2013; Simon *et al.* 2002; Vlenterie *et al.* 2021), whereas others have not found this association (Einarson *et al.* 2001, 2003; Kulin *et al.* 1998; Sivojelezova *et al.* 2005; Venkatesh *et al.* 2016). Multiple meta-analyses have found an association between prenatal antidepressant exposure and preterm delivery (Chang *et al.* 2020; Eke *et al.* 2016; Huang *et al.* 2014; Huybrechts *et al.* 2014b; Ross *et al.* 2013; Vlenterie *et al.* 2021) and low birthweight (Huang *et al.* 2014; Ross *et al.* 2013). However, interpretation is complicated by other reports that prematurity and low birthweight are associated with prenatal maternal depression and anxiety (Fekadu Dadi *et al.* 2020; Ghimire *et al.* 2021; Grigoriadis *et al.* 2018; Jarde *et al.* 2016), and there is a lack of precision in efforts to control for the confounding effect of maternal mental illness in studies to date. As a result, no definitive conclusions can be drawn as to whether antidepressant use during gestation conveys an adverse impact on fetal growth or the timing of parturition.

Finally, concerns have been expressed about neonatal SSRI syndromes, manifested by a variable constellation of transient respiratory, cardiovascular, gastrointestinal, motor, and central nervous system symptoms (Moses-Kolko *et al.* 2005). A recent meta-analysis (Kautzky *et al.* 2022), identifying only 33 qualifying controlled studies among 3,025 published reports, confirmed a statistically significant association between serotonin reuptake inhibitor exposure and symptoms of so-called poor neonatal adaptation syndrome; however, the authors bemoaned the fact that the "inherently low data quality in this research domain and insufficiently defined samples and outcomes" (p. 6) left them unable to draw conclusions about the clinical relevance of these data. Indeed, close scrutiny of this literature reveals many methodological shortcomings, including failure to adequately control for confounding and susceptibility to rater bias and ascertainment bias.

Debate has also focused on a more serious neonatal concern: a putative connection between late-pregnancy SSRI exposure and persistent pulmonary hypertension of the neonate (PPHN). A case-control study (Chambers *et al.* 2006) of 1,213 neonates (377 with PPHN) reported findings supporting an association between SSRI exposure and PPHN (OR

= 6.1). This lone report led the FDA in July 2006 to issue a Public Health Advisory regarding this reported link to PPHN (U.S. Food and Drug Administration 2006). Five years later, after a series of both positive and negative studies, the FDA issued an update advising that "conflicting studies [are] . . .making it unclear whether use of SSRIs during pregnancy can cause PPHN" (U.S. Food and Drug Administration 2011). Two meta-analyses (Masarwa *et al.* 2019; Ng *et al.* 2019) of the 11 studies to date reported a significant association (ORs = 1.52 and 1.82) between SSRI exposure and PPHN; Ng *et al.* (2019) estimated the risk difference attributable to antidepressant exposure at 0.619 per 1,000 live deliveries.

Pharmacokinetic data regarding the placental passage of SSRI antidepressants remain limited. However, existing studies have demonstrated that mean fetal/maternal ratios for numerous SSRIs and their active metabolites are uniformly less than 1.0, although considerable differences exist between agents (Heinonen *et al.* 2021; Hendrick *et al.* 2003; Rampono *et al.* 2009).

Published reports pertaining to SSRIs and lactation now encompass the largest dataset for medications during breastfeeding, including infant serum measures, breast milk concentrations, and pharmacokinetic studies of excretion. There are now published investigations for all of the SSRIs including sertraline (Altshuler *et al.* 1995; Birnbaum *et al.* 1999; Dodd *et al.* 2000; Epperson *et al.* 1997, 2001; Hendrick *et al.* 2001a; Kristensen *et al.* 1998; Mammen *et al.* 1997; Schoretsanitis *et al.* 2019; Stowe *et al.* 1997, 2003; Wisner *et al.* 1998), fluoxetine (Birnbaum *et al.* 1999; Burch and Wells 1992; Hendrick *et al.* 2001b; Kristensen *et al.* 1999; Lester *et al.* 1993; Suri *et al.* 2002; Taddio *et al.* 1996; Yoshida *et al.* 1998a), paroxetine (Birnbaum *et al.* 1999; Hendrick *et al.* 2001a; Ohman *et al.* 1999; Spigset *et al.* 1996; Stowe *et al.* 2000), escitalopram (Rampono *et al.* 2006; Weisskopf *et al.* 2020), fluvoxamine (Hendrick *et al.* 2001a; Piontek *et al.* 2001; Wright *et al.* 1991), and citalopram (Jensen *et al.* 1997; Schmidt *et al.* 2000; Schoretsanitis *et al.* 2019; Spigset *et al.* 1997; Weisskopf *et al.* 2020). Although infant follow-up data are limited, only a few isolated cases of adverse effects have been reported. Long-term neurobehavioral studies of infants exposed to SSRI antidepressants during lactation warrant continued examination. The pharmacokinetic profiles of breast milk excretion, including delineation of distribution gradients and time gradients, are best defined for sertraline (Stowe *et al.* 1997, 2003), paroxetine (Stowe *et al.* 2000), escitalopram (Weisskopf *et al.* 2020), and fluoxetine (Suri *et al.* 2002). These studies indicate that quantitative infant SSRI exposure during lactation is considerably lower than transplacental exposure.

Serotonin-Norepinephrine Reuptake Inhibitors

Although lagging considerably behind the SSRIs, reproductive safety data for serotonin-norepinephrine reuptake inhibitors (SNRIs) are steadily accruing. A multicenter case-control study including 71 prenatal venlafaxine exposures reported significantly higher rates of numerous malformations (ORs = 3.34-5.26) (Anderson *et al.* 2020). Previous studies collectively encompassing 862 venlafaxine exposures observed 91 (10.6%) major malformations among exposed infants (Einarson *et al.* 2001; GlaxoSmithKline 2005; Polen *et al.* 2013). As previously noted in the SSRI discussion, surveillance biases, particularly with respect to cardiovascular defects, cannot be ruled out. A Scandinavian cohort study including 1,512 duloxetine-exposed pregnancies found no evidence of increased risk for birth defects (OR = 0.98) (Ankarfeldt *et al.* 2021). An earlier study including 165 live births to women using duloxetine throughout pregnancy reported 3 (1.8%) major malformations (Einarson *et al.* 2012). To date, there are no reports regarding birth defect rates associated with exposure to desvenlafaxine or levomilnacipran.

There have been reports on neonatal and developmental outcomes following prenatal exposure to duloxetine and venlafaxine. A single report followed an infant until 9 months after in utero exposure to duloxetine, with no abnormalities in cognitive, language, motor, and psychomotor development (Bellantuono *et al.* 2013). Likewise, children exposed to venlafaxine in utero had no difference in IQ or behavior compared with children of nondepressed mothers (Nulman *et al.* 2012).

A nested case-control study reported that maternal exposure to SNRI antidepressants after the twentieth week of pregnancy was associated with an increased risk for hypertensive disorders of pregnancy (OR = 2.57; 95% CI, 1.34-4.93), with an even higher sixfold increase among mothers receiving venlafaxine at dosages exceeding 187.5 mg/day (Newport *et al.* 2016).

Prenatal pharmacokinetic data are limited. High rates of placental transfer (umbilical cord concentrations in excess of maternal concentrations) have been reported for venlafaxine (Hendrick *et al.* 2003) and for its active metabolite, desvenlafaxine (Hendrick *et al.* 2003; Rampono *et al.* 2009). Duloxetine has a single case report of a cord/maternal serum concentration ratio of 0.12, which suggests a low rate of placental transfer (Boyce *et al.* 2011).

Lactation data also remain limited. Best studied are venlafaxine/desvenlafaxine, for which three studies (Ilett *et al.* 1998; Newport *et al.* 2009; Rampono *et al.* 2011; Schoretsanitis *et al.* 2019) encompassing 26 mother-infant nursing dyads have reported relative infant doses (RIDs) of 6.8%-8.1%, which is within the notional 10% presumed safety level (Hendrick *et al.* 2003; Rampono *et al.* 2009). A single case report and a small series of 6 women receiving duloxetine therapy during lactation reported RIDs of less than 1% (Boyce *et al.* 2011; Lobo *et al.* 2008). There are no published lactation data for levomilnacipran.

Atypical Antidepressants

Reproductive safety data are more limited for the so-called atypical antidepressants (i.e., bupropion, mirtazapine, nefazodone, trazodone, vilazodone, and vortioxetine). Prospective reports of first-trimester use of these agents consist of 2,550 bupropion exposures producing 56 (2.2%) children with major malformations (Boshier *et al.* 2003; Briggs *et al.* 2005; Chun-Fai-Chan *et al.* 2005; Cole *et al.* 2007; GlaxoSmithKline 2005), 404 trazodone exposures with 10 (2.5%) major malformations (Briggs *et al.* 2005; GlaxoSmithKline 2005; McElhatton *et al.* 1996), 140 nefazodone exposures with 2 (1.4%) major malformations (GlaxoSmithKline 2005), 508 mirtazapine exposures with 14 (2.8%) major malformations (Djulus *et al.* 2006; GlaxoSmithKline 2005; Smit *et al.* 2015; Winterfeld *et al.* 2015), and a combined report of 121 nefazodone or trazodone exposures with 2 (1.7%) major malformations (Einarson *et al.* 2003). A lone case report of vilazodone use in pregnancy resulted in a full-term, healthy neonate (Morrison 2014). There are no published data on prenatal vortioxetine exposure. Neurodevelopmental data following prenatal exposure to atypical antidepressants are lacking, as are prenatal pharmacokinetic studies.

Lactation data also remain limited. The sole report of bupropion in nursing infants noted that the drug could not be detected in the plasma of a nursing infant (Briggs *et al.* 1993). Five reports totaling 55 neonates exposed to mirtazapine have been reported, with no adverse outcomes and low RIDs (Aichhorn *et al.* 2004; Klier *et al.* 2007; Kristensen *et al.* 2007; Smit *et al.* 2015; Tonn *et al.* 2009). There are no published lactation data for vilazodone or vortioxetine.

Mood Stabilizers

Lithium

Early retrospective data suggested that lithium exposure was associated with a 400-fold increase in cardiac malformations, specifically Ebstein's anomaly (Nora *et al.* 1974; Weinstein and Goldfield 1975). Subsequent large studies confirmed the concern for teratogenicity, but at a much lower magnitude (L. S. Cohen *et al.* 1994). Altshuler *et al.* (1996) estimated a 20-fold increase in the risk for Ebstein's anomaly, from 1:20,000 to 1:1,000 after prenatal lithium exposure. A U.S. cohort study (Patorno *et al.* 2017) observed a threefold risk increase for cardiac malformations when daily dosage exceeded 900 mg. Two recent meta-analyses (Fornaro *et al.* 2020; Munk-Olsen *et al.* 2018) reported that lithium exposure was associated with an even lower risk for overall major malformations (OR = 1.71-203); only one of these studies (Fornaro *et al.* 2020) found that lithium exposure was associated with cardiac defects (OR = 3.99). When lithium is used in pregnancy, a fetal echocardiogram between gestational weeks 18 and 20 is recommended. Deciding whether to continue lithium in pregnancy depends on the severity and course of the patient's illness and the time point of the exposure during gestation. Discontinuing lithium therapy once cardiogenesis nears completion at 9-11 weeks' gestation may be ill-advised.

Neurodevelopment sequelae of prenatal lithium exposure have not been demonstrated; however, evidence remains limited (Forsberg *et al.* 2018; Jacobson *et al.* 1992; Schou 1976; van der Lugt *et al.* 2012).

Two recent meta-analyses reported reassuring data on obstetrical complications following lithium exposure. In a comparison with illness-matched control subjects, lithium in pregnancy did not confer increased risk of miscarriage (Fornaro *et al.* 2020) or preeclampsia, gestational diabetes, fetal distress, postpartum hemorrhage, cesarean section, preterm birth, low birthweight, or small-for-gestational-age birth (Munk-Olsen *et al.* 2018). A large U.S. cohort study reported no increased risk of ischemic placental disease, preterm birth, or small-for-gestational-age birth (J. M. Cohen *et al.* 2019). Conversely, a recent retrospective cohort study found that prenatal lithium exposure (n = 119) was associated with increased fetal growth and birthweight (Poels *et al.* 2021).

Lithium's narrow therapeutic index raises concern for acute perinatal toxicity. In a pooled analysis of lithium placental passage and neonatal outcomes (Newport *et al.* 2005), we determined that 1) higher neonatal lithium concentrations were associated with significantly lower Apgar scores, longer hospital stays, and higher rates of CNS and neuromuscular complications; 2) umbilical cord (i.e., fetal) plasma concentrations were uniformly equivalent to maternal concentrations, confirming lithium's rapid transplacental equilibration; and 3) withholding lithium therapy for only 24-48 hours lowered lithium concentrations by 0.28 mEq/L. By contrast, a recent cohort study (Molenaar *et al.* 2021) observed no association between lithium levels and neonatal complications; however, the discrepancy with the earlier study may be attributable to the narrower range of observed lithium concentrations.

Alterations in renal clearance across pregnancy and the potential for abrupt volume changes during delivery mandate careful monitoring of lithium levels during pregnancy and at delivery. One study assessed longitudinally the peripartum pattern of maternal serum lithium, observing a decrease from the preconception level during the first and second trimesters and a gradual increase in the third trimester toward the preconception level (Wesseloo *et al.* 2017).

The existing database regarding lithium and lactation encompasses 43 mother-infant dyads (Bogen *et al.* 2012; Frew 2015; Fries 1970; Marin Gabriel *et al.* 2018; Moretti *et al.* 2003; Schou and Amdisen 1973; Skausig and Schou 1977; Sykes *et al.* 1976; Tanaka *et al.* 2008; Tunnessen and Hertz 1972; Viguera *et al.* 2007a; Weinstein and Goldfield 1969; Woody *et al.* 1971). Adverse events, including lethargy, hypotonia, hypothermia, cyanosis, electrocardiogram changes, poor feeding, slow growth, gross and fine motor delay, and elevated thyroid-stimulating hormone level, were reported in 6 (15%) of the 43 children collectively included in these case reports of lithium exposure via lactation. The American Academy of Pediatrics (Sachs and Committee on Drugs 2013) recommends monitoring growth and neurodevelopment in infants exposed to lithium during lactation. The hydration status of nursing infants of mothers taking lithium should also be carefully monitored (Llewellyn *et al.* 1998). Lithium

transfer to the infant from breast milk is variable, with lithium concentrations in nursing infants ranging from 5% to 67% of maternal levels (Newmark *et al.* 2019). The largest pharmacokinetic study calculated lithium's milk-to-plasma ratio as 53% and infant-to-maternal plasma ratio as 24% (Viguera *et al.* 2007a).

Lamotrigine

Reproductive safety data regarding lamotrigine have rapidly accrued and compare favorably with those of other mood stabilizers (Weston *et al.* 2016). Malformation rates after first-trimester lamotrigine exposure are consistent with those of the general population (Campbell *et al.* 2014; Cunnington *et al.* 2011; Dominguez-Salgado *et al.* 2004; GlaxoSmithKline 2007; Holmes *et al.* 2006; Meador *et al.* 2006; Molgaard-Nielsen and Hviid 2011; Morrow *et al.* 2006; Sabers *et al.* 2004; Vajda *et al.* 2003). A report by the North American Pregnancy Registry (Holmes *et al.* 2006) noted a high rate of orofacial clefts (0.89% of 564 exposures); the collective rate of orofacial clefts in the other registries was only 0.10% (3 per 2,956 exposures) (Dominguez-Salgado *et al.* 2004; GlaxoSmithKline 2007; Meador *et al.* 2006; Molgaard-Nielsen and Hviid 2011; Morrow *et al.* 2006; Sabers *et al.* 2004; Vajda *et al.* 2003). The UK Epilepsy and Pregnancy Register reported a higher risk of malformations at maternal dosages exceeding 200 mg/day (Morrow *et al.* 2006), although this finding was not confirmed in subsequent analyses (GlaxoSmithKline 2007; Molgaard-Nielsen and Hviid 2011; Patorno *et al.* 2017). Despite these reassuring findings, folate supplementation is recommended for all women of childbearing age who are taking any antiepileptic drug, including lamotrigine.

Prospective neurodevelopmental data have been consistently favorable for prenatal lamotrigine exposure (Baker *et al.* 2015; Coste *et al.* 2020; McVearry *et al.* 2009; Meador *et al.* 2006, 2009, 2011; Nadebaum *et al.* 2011b); however, a meta-analysis (Veroniki *et al.* 2017b) reported that lamotrigine exposure is associated with increased risk for autism (OR = 8.88; 95% CI, 1.28-112), although the wide confidence interval suggests caution in interpreting these results.

Lamotrigine clearance steadily increases across the gestational period (de Haan *et al.* 2004; Fotopoulou *et al.* 2009; Franco *et al.* 2008; Pennell *et al.* 2004, 2008; Petrenaite *et al.* 2005; Polepally *et al.* 2014; Reisinger *et al.* 2013; Tran *et al.* 2002), with changes evident as early as week 5 of gestation (Karanam *et al.* 2018); lamotrigine clearance abruptly declines after delivery (Ohman *et al.* 2000; Pennell *et al.* 2004; Polepally *et al.* 2014; Tran *et al.* 2002). Multiple dosage increases during pregnancy followed by a postpartum decrease may thus be necessary. Neonatal lamotrigine concentrations are equal to maternal concentrations (Myllynen *et al.* 2003; Ohman *et al.* 2000; Paulzen *et al.* 2015; Sathanandar *et al.* 2000; Tomson *et al.* 1997), indicating complete placental passage.

There have been no reports of acute adverse obstetrical or neonatal outcomes in association with prenatal lamotrigine exposure.

Reports regarding lamotrigine and lactation (Bedussi *et al.* 2018; Clark *et al.* 2013; GlaxoSmithKline 2007; Kacirova *et al.* 2019a; Liporace *et al.* 2004; Morin and Chevalier 2017; Newport *et al.* 2008c; Nordmo *et al.* 2009; Ohman *et al.* 2000; Page-Sharp *et al.* 2006; Rambeck *et al.* 1997; Tomson *et al.* 1997) encompass 145 mother-infant nursing dyads. The two largest lamotrigine lactation studies, collectively comprising 100 mother-infant pairs (Birnbaum *et al.* 2020; Newport *et al.* 2008b), reported mean infant-to-maternal

plasma ratios of 18.3%-28.9%. Adverse events were reported for 10 (6.9%) of these children, including apneic episodes (Nordmo *et al.* 2009), 7 infants with benign thrombocytosis (Newport *et al.* 2008b), anemia (Bedussi *et al.* 2018), weight loss, and dehydration (Morin and Chevalier 2017). In addition, the French Pharmacovigilance Database reported adverse reactions (sedation, hypotonia, weight loss, and liver damage) in 6 infants breastfed by mothers taking lamotrigine (Soussan *et al.* 2014). Long-term neurobehavioral outcomes have not been studied in nursing infants exposed to lamotrigine.

Valproate (Valproic Acid)

Prenatal exposure to valproate has been associated with multiple congenital malformations, including neural tube, cardiac, orofacial or craniofacial, and skeletal and limb defects, with an OR of 10.93 for overall major malformations (Weston *et al.* 2016). Two meta-analyses confirmed that valproate's teratogenicity exceeds that of other anticonvulsants (Veroniki *et al.* 2017a; Weston *et al.* 2016). Risks for spina bifida and for limb defects are estimated at 1%-2% (10-20 times greater than in the general population) (Bjerkedal *et al.* 1982; Centers for Disease Control and Prevention 1992; Rosa 1991) and 0.42% (i.e., 6.17 times higher than in the general population) (Rodriguez-Pinilla *et al.* 2000), respectively. Dosages higher than 1,500 mg/day have been linked with greatest risk (Weston *et al.* 2016). One group recommend not exceeding 1,000 mg/day and maintaining maternal serum concentrations below 70 mg/mL to reduce teratogenic risk (Kaneko *et al.* 1999). Valproate antagonism of folate activity may underlie the risk for both spina bifida and fetal valproate syndrome, a condition characterized by a distinctive pattern of facial dysmorphism and other malformations (McMahon and Braddock 2001; Moore *et al.* 2000). A case-control study of children with and without fetal anticonvulsant syndrome, who had all been exposed to an AED during gestation, found a significantly higher rate of homozygosity for a mutation in the methylenetetrahydrofolate reductase gene in the mothers of affected children (Dean *et al.* 1999).

Neurodevelopmental outcomes in offspring associated with prenatal valproate exposure are of equal concern (Baker *et al.* 2015; M. J. Cohen *et al.* 2013; Meador *et al.* 2009, 2013; Shallcross *et al.* 2011; Veiby *et al.* 2013), particularly in relation to verbal cognition (McVearry *et al.* 2009; Meador *et al.* 2011; Nadebaum *et al.* 2011a, 2011b). Prenatal valproate exposure has been associated with a 7-to 10-point reduction in IQ at 6 years of age (Meador *et al.* 2013), in line with findings at 3 (Meador *et al.* 2009), 3.6 (Coste *et al.* 2020), and 4.5 years (Meador *et al.* 2012). A recent Swedish population-based study (Wiggs *et al.* 2020) with 17 years of follow-up data estimated that prenatal valproate exposure confers a 2.3-fold higher risk for autism spectrum disorder and 1.7-fold higher risk for ADHD. The highest risk of neurodevelopmental disorders was found for dosages higher than 1,100 mg/day (Coste *et al.* 2020).

Valproate exposure during gestation is also associated with negative obstetrical outcomes, such as fetal loss (Veroniki *et al.* 2017a) and numerous fetal and neonatal toxicities, including hepatotoxicity (Kennedy and Koren 1998), coagulopathies (Mountain *et al.* 1970), and neonatal hypoglycemia (Ebbesen *et al.* 2000; Thisted and Ebbesen 1993). However, in a U.S. cohort study, prenatal valproate (n = 2,398) did not confer increased risk of ischemic placental disease, preterm birth, or small-for-gestational-age birth (J. M. Cohen *et al.* 2019).

Maternal valproate concentrations steadily decline across pregnancy (Yerby *et al.* 1990, 1992), especially during the final month (Nau *et al.* 1982b; Otani 1985; Philbert *et al.* 1985). Thus, dosage increases may be necessary to maintain therapeutic efficacy during pregnancy. Umbilical cord concentrations at delivery are greater than or equal to maternal concentrations (Froescher *et al.* 1984b; Philbert *et al.* 1985; Yerby *et al.* 1990, 1992).

The literature regarding valproate and lactation encompasses 72 mother-infant dyads (Alexander 1979; Bardy *et al.* 1982a; Dickinson *et al.* 1979; Froescher *et al.* 1981; Govindan and Mandadi 2021; Kacirova *et al.* 2019b;

Nau *et al.* 1981; Piontek *et al.* 2000; Stahl *et al.* 1997; Tsuru *et al.* 1988; von Unruh *et al.* 1984; Wisner and Perel 1998). Two adverse events were reported: thrombocytopenia and anemia (Stahl *et al.* 1997) and patchy hair loss (Govindan and Mandadi 2021). Valproate milk-to-plasma ratios are uniformly low, and serum concentrations of nursing infants are 2%-40% of maternal concentrations (Alexander 1979; Bardy *et al.* 1982a; Kacirova *et al.* 2019b; Piontek *et al.* 2000; Stahl *et al.* 1997; von Unruh *et al.* 1984; Wisner *et al.* 1996b). Breastfeeding exposure to valproate was not associated with cognitive delay in children at 3 (Meador *et al.* 2010) or 6 years of age (Meador *et al.* 2014).

Because of grave safety concerns, valproate should be used in women of childbearing age only as a last resort. If valproate must be used during pregnancy, its risk may be reduced by not exceeding a daily dosage of 1,000 mg and a serum concentration of 70 mg/mL. High-dose folate supplementation (4-5 mg/day) is recommended in valproate-treated women of reproductive age, although there is no conclusive evidence that such dosing reduces the risks associated with prenatal valproate exposure. Preliminary evidence that aspects of fetal valproate syndrome other than neural tube defects may be associated with valproate's antagonism of folate metabolism suggests that folate supplementation should be administered not only in the first trimester but throughout gestation. Because of the potential for valproate-associated neonatal coagulopathies, oral vitamin K supplementation (10-20 mg/day) may be considered during the final month of gestation. Prenatal surveillance for congenital abnormalities should include maternal serum alpha-fetoprotein, fetal echocardiography, and a level 2 ultrasound at approximately 16-18 weeks' gestation. Genetic screening of valproate-treated women for methylenetetrahydrofolate reductase mutations warrants future consideration. Although valproate therapy during lactation appears to be better tolerated, monitoring platelet count and serum liver enzymes of nursing infants is recommended.

Carbamazepine

Carbamazepine is associated with many of the same risks as valproate during gestation, although with less frequency or severity. For example, meta-analyses (Veroniki *et al.* 2017a; Weston *et al.* 2016) have found that the risk for major malformations (OR = 1.37-2.01) associated with carbamazepine exposure was markedly lower than that attributed to valproate (OR = 10.93) (Weston *et al.* 2016). Carbamazepine exposure confers a 0.5%-1.0% risk for neural tube defects (Rosa 1991), approximately half the magnitude of valproate (Lindhout and Schmidt 1986; Rosa 1991). Periconceptional folate supplementation has been associated with a lower rate of neural tube defects among children exposed to carbamazepine prenatally (Hernandez-Diaz *et al.* 2001). Heightened teratogenic risk has been reported at daily dosages exceeding 1,000 mg (Campbell *et al.* 2013; Tomson *et al.* 2011).

Systematic studies have generally failed to produce evidence of developmental delay in children exposed to carbamazepine prenatally (Baker *et al.* 2015; McVearry *et al.* 2009; Meador *et al.* 2006, 2009, 2011; Nadebaum *et al.* 2011b). However, data from the Swedish medical register (Wiggs *et al.* 2020) reported that first-trimester carbamazepine exposure (*n* = 1,417) was associated with a small elevated risk of autism spectrum disorder (hazard ratio = 1.26).

Obstetrical outcome data for carbamazepine have been favorable. Neonatal hepatotoxicity has been reported in one carbamazepine-exposed infant (Frey *et al.* 2002); however, a recent U.S. cohort study found no association between carbamazepine exposure (*n* = 1,232) and risk of ischemic placental disease, preterm birth, or small-for-gestational-age birth (J. M. Cohen *et al.* 2019).

Some investigators have reported significant increases in carbamazepine clearance during the third trimester of pregnancy (Battino *et al.* 1982; Dam *et al.* 1979; Lander *et al.* 1981), but others have found no changes (Bardy *et al.* 1982b; Johnson *et al.* 2014; Otani 1985; Reisinger *et al.* 2013; Yerby *et al.* 1985). Umbilical-cord-to-maternal plasma ratios are 0.5-0.8, a lower placental transfer than for other anticonvulsants (Nau *et al.* 1982a; Yerby *et al.* 1990, 1992).

The literature on carbamazepine and lactation encompasses 144 mother-infant pairs (Antonucci *et al.* 2018; Birnbaum *et al.* 2020; Brent and Wisner 1998; Frey *et al.* 1990, 2002; Froescher *et al.* 1984a; Kacirova *et al.* 2021b;

Kaneko *et al.* 1982; Kok *et al.* 1982; Kuhnz *et al.* 1983; Merlob *et al.* 1992; Niebyl *et al.* 1979; Pynnonen and Sillanpaa 1975; Pynnonen *et al.* 1977; Wisner and Perel 1998). Adverse events were reported in 9 (6.3%) children, including irritability (Kok *et al.* 1982), "hyperexcitable" presentation (Kuhnz *et al.* 1983), cholestatic hepatitis (Frey *et al.* 1990, 2002), poor nursing effort (Froescher *et al.* 1984a), increased serum concentration of g-glutamyl transpeptidase but no overt clinical sequelae (Merlob *et al.* 1992), "seizurelike" phenomenon (Brent and Wisner 1998), and recurrent regurgitation and vomiting (Antonucci *et al.* 2018). Serum carbamazepine concentrations range from undetectable to 65% of the maternal level (Birnbaum *et al.* 2020; Brent and Wisner 1998; Kacirova *et al.* 2021b; Kok *et al.* 1982; Merlob *et al.* 1992; Pynnonen and Sillanpaa 1975; Pynnonen *et al.* 1977; Wisner and Perel 1998). No adverse effects on cognitive functions at 3 (Meador *et al.* 2010) or 6 years of age (Meador *et al.* 2014) were observed in children exposed through breast milk.

Although the risks associated with prenatal carbamazepine exposure are better than those for valproate, clinical recommendations are similar. Carbamazepine should be avoided in pregnancy, especially during the first trimester. Folate supplementation (4-5 mg/day) is recommended throughout the reproductive years because of the high prevalence of unintended pregnancies. Prenatal surveillance for congenital abnormalities includes maternal serum alpha-fetoprotein, fetal echocardiography, and a level 2 ultrasound at approximately 16-18 weeks' gestation. Reports of hepatic dysfunction in nursing infants raise concern; thus, periodic assays of blood counts and serum liver enzymes of nursing infants are recommended.

Other Antiepileptic Drugs

Several other antiepileptic drugs are often used as off-label treatments for bipolar disorder, despite the lack of evidence supporting their efficacy. In the absence of efficacy, these agents should not be used to manage bipolar disorder in women of childbearing

age. However, because they are often inadvisably used for this purpose, a brief summary of their reproductive safety data is provided.

Oxcarbazepine

Reproductive safety data for oxcarbazepine are limited. A 2016 meta-analysis (Weston *et al.* 2016) found that the risk of major malformations associated with oxcarbazepine exposure is not different from that of the general population (2.39%). Another meta-analysis (Veroniki *et al.* 2017b) reported an increased risk for autism spectrum disorder (OR = 13.51; 95% CI, 1.28-221.40) among children exposed to oxcarbazepine during pregnancy; however, the wide confidence interval suggests caution in interpreting these results. A recent U.S. cohort study did not show increased risk of ischemic placental disease, preterm birth, or small-for-gestational-age birth among 1,109 infants from oxcarbazepine-exposed pregnancies (J. M. Cohen *et al.* 2019). Serum levels in nursing infants (*n* = 8) have to date been reported as undetectable, with no adverse effects noted (Birnbaum *et al.* 2020).

Topiramate

A 2016 meta-analysis (Weston *et al.* 2016) of prenatal topiramate exposure found a fourfold increase in the risk for major malformations among 359 exposed infants. A subsequent study (*N* = 2,425) observed increased risk for oral clefts (OR = 2.9), with a fivefold increase for daily dosages exceeding 100 mg (Hernandez-Diaz *et al.* 2018). Obstetrical outcome data have been more favorable, with a recent U.S. cohort study (*n* = 2,280) finding no association with risk of ischemic placental disease, preterm birth, or small-for-gestational-age birth (J. M. Cohen *et al.* 2019). Topiramate concentrations in 19 topiramate-exposed neonates were 51% of maternal levels (Kacirova *et al.* 2021a). Plasma levels in nursing infants were all undetectable in a recent study of topiramate in lactation (Birnbaum *et al.* 2020). Another study reported one adverse event, diarrhea, in 7 infants exposed to topiramate via breast milk (Westergren *et al.* 2014).

Gabapentin

A U.S. cohort study using a Medicaid database reported an increased risk for cardiac malformation (OR = 1.40) but no difference in overall malformation rates among gabapentin-exposed children (Patorno *et al.*

2020). The same study reported increased rates of preterm birth (OR = 1.28), small-for-gestational-age birth (OR = 1.17), and neonatal intensive care unit (NICU) admission (OR = 1.35) in association with gabapentin exposure. No adverse effects were reported among 8 infants exposed to gabapentin during lactation (Birnbaum *et al.* 2020).

Antipsychotics

Second-Generation A5ntipsychotics

The second-generation antipsychotics (SGAs) have emerged as first-line agents for psychotic disorders and are often used for other psychiatric indications, including bipolar disorder, anxiety disorders, and treatment-resistant depression. Although perinatal use of SGAs is rapidly expanding, the reproductive safety database is lagging. Findings from recent studies, albeit limited, are reassuring and suggest that SGAs may not be major teratogens (L. S. Cohen *et al.* 2016; Coughlin *et al.* 2015; Ellfolk *et al.* 2021; Huybrechts *et al.* 2016; Viguera *et al.* 2021). A neurodevelopmental study reported a transient delay in cognitive, motor, social-emotional, and adaptive behavior in SGA-exposed infants that resolved by 12 months of age (Peng *et al.* 2013). A recent population-based cohort study did not find an elevated risk of autism spectrum disorder or ADHD in association with prenatal SGA exposure (Wang *et al.* 2021).

Some studies have linked prenatal SGA use with adverse obstetrical outcomes including preterm delivery (Coughlin *et al.* 2015; Sadowski *et al.* 2013) and poor neonatal adaptation (Habermann *et al.* 2013; Sadowski *et al.* 2013), although others have not (Vigod *et al.* 2015; Wang *et al.* 2021). The metabolic side effects associated with SGAs warrant concern for gestational diabetes mellitus; however, a recent systematic review that included 10 studies found no association between prenatal SGA therapy, considered collectively, and gestational diabetes mellitus (Uguz 2019).

Clozapine

Reproductive safety data for clozapine, the oldest SGA, are limited primarily to case reports, case series, and small case-control studies (Thanigaivel *et al.* 2022). Anecdotal reports of minor anomalies include cephalohematoma, hyperpigmentation folds, and a coccygeal dimple (Stoner *et al.* 1997); delayed peristalsis (Moreno-Bruna *et al.* 2012); transient low-grade fever in an infant also exposed to lithium (Stoner *et al.* 1997); and poor muscle tone in a neonate also exposed to lorazepam (Di Michele *et al.* 1996). In a review of 61 children exposed to clozapine and other psychotropics, Dev and Krupp (1995) reported 5 children with congenital malformations and 5 with neonatal complications. In contrast, a review encompassing 620 children with prenatal clozapine exposure found no specific pattern of congenital malformations (Mehta and Van Lieshout 2017). A study of neurodevelopmental sequelae reported a higher rate of delayed development at 2 months and 6 months of age that resolved by 12 months among clozapine-exposed infants in comparison to those exposed to other SGAs (Shao *et al.* 2015).

A recent study using data from VigiBase, the world's largest pharmacovigilance database, found no evidence of poorer obstetrical outcomes when comparing clozapine exposure to other antipsychotics (Beex-Oosterhuis *et al.* 2020). However, other reports have linked clozapine with maternal gestational diabetes (Ellfolk *et al.* 2020; Galbally *et al.* 2020).

A recent investigation reported only partial placental transfer of clozapine ($n = 4$), with no evidence of accumulation during breastfeeding in the first 33 neonatal hours ($n = 1$) (Imaz *et al.* 2018). This finding is in contrast to a single case report describing similar medication concentrations in maternal serum and amniotic fluid but markedly higher concentrations in fetal serum and breast milk (Barnas *et al.* 1994), leading the authors to conclude that clozapine accumulates in the fetal circulation and breast milk. Although only one case of agranulocytosis has been reported in a clozapine-exposed infant, this potential risk and the requisite laboratory monitoring limit clozapine's perinatal utility (Dev and Krupp 1995; Uguz 2016).

Quetiapine

Reproductive safety studies for quetiapine, one of the more frequently prescribed SGAs during pregnancy (Halfdanarson *et al.* 2017; Moreno-Bruna *et al.* 2012), are outpacing other SGAs with largely reassuring findings. Specifically, two cohort studies from a nationwide Medicaid database (*n* = 4,221) (Huybrechts *et al.* 2016) and a national registry (*n* = 155) (L. S. Cohen *et al.* 2016, 2018) found no evidence linking quetiapine exposure with cardiac or other malformations. Data regarding the neurodevelopmental effects of quetiapine exposure are limited to one case report in which an infant was reported to exhibit normal development at 4.5 months of age (Lee *et al.* 2004).

In the Newport *et al.* (2007a) study of antipsychotic placental passage, quetiapine concentrations among neonates (*n* = 21) were 23% of maternal concentrations, the lowest placental passage rate among psychotropics studied to date.

Twelve cases of quetiapine use during lactation estimated the nursing infant dosage at 0.02%-0.43% of the weight-adjusted maternal daily dosage, with no adverse effects reported among the exposed infants (Aydin *et al.* 2015; Lee *et al.* 2004; Rampono *et al.* 2007; Yazdani-Brojeni *et al.* 2018).

Olanzapine

In a published birth registry from the Lilly Worldwide Pharmacovigilance Safety Database, 610 prospectively identified pregnancies exposed to olanzapine resulted in 9.8% premature births, 9.3% spontaneous abortions, 8% perinatal conditions, and 4.4% congenital anomalies (Brunner *et al.* 2013). A prospective study comparing outcomes among 151 pregnant women with SGA exposure (olanzapine, *n* = 0) to 151 pregnant control subjects reported no differences in rates of spontaneous abortion, stillbirth, major malformations, prematurity, or low birthweight (McKenna *et al.* 2005). In this study, one child exposed to an SGA (olanzapine) was observed to have major malformations (a series of midline defects including an oral cleft, encephalocele, and aqueductal stenosis). A meta-analysis reported a malformation rate of 3.5% among 1,090 olanzapine-exposed infants, comparing favorably to other SGAs (Ennis and Damkier 2015). In a large cohort study of Medicaid-insured women, olanzapine exposure during the first trimester (*n* = 1,394) did not significantly elevate the risk of major congenital or cardiac malformations when compared to unexposed pregnancies (Huybrechts *et al.* 2016).

In a study of antipsychotic placental passage rates and neonatal outcomes (Newport *et al.* 2007a), umbilical cord concentrations in olanzapine-exposed neonates (*n* = 4) were 72.1% of maternal concentrations.

Case reports of 41 infants exposed to olanzapine during lactation with no evidence of infant toxicity currently appear in the literature (Croke *et al.* 2002; Friedman and Rosenthal 2003; Gardiner *et al.* 2003; Gilad *et al.* 2011; Goldstein *et al.* 2000; Kirchheiner *et al.* 2000; Stiegler *et al.* 2014; Whitworth *et al.* 2010). The Lilly Safety Database reported on 62 breastfeeding mother-infant dyads with a 15.6% rate of adverse events, identified as somnolence, irritability, tremors, and insomnia (Brunner *et al.* 2013). Pharmacokinetic studies of olanzapine exposure during lactation have reported that plasma concentrations were undetectable in infants during nursing (Gardiner *et al.* 2003; Kirchheiner *et al.* 2000; Stiegler *et al.* 2014) and that the median infant daily dosage via breastfeeding was approximately 0.74%-1.8% of the maternal dosage (Ambresin *et al.* 2004; Aydin *et al.* 2015; Brunner *et al.* 2013; Croke *et al.* 2002; Gardiner *et al.* 2003).

Risperidone and Paliperidone

A meta-analysis reported a 5.1% malformation rate among 432 risperidone-exposed infants (Ennis and Damkier 2015). Another study of pregnancy outcomes for several SGAs (McKenna *et al.* 2005) reported no major malformations among 49 risperidone-exposed infants. In contrast, a cohort study of Medicaid-insured women indicated that risperidone exposure (*n* = 1,566) may carry a small risk for congenital malformations (OR = 1.26), which was not seen for other antipsychotics in the study (Huybrechts *et al.* 2016). A lone case report of paliperidone palmitate, the long-acting injectable formulation of paliperidone, reported no adverse obstetrical outcome (Ozdemir *et al.* 2015). There are no available data on the neurodevelopmental effects of risperidone or paliperidone exposure.

Pharmacokinetic studies have reported placental passage concentrations among neonates (*n* = 6) of 49.2% (Newport *et al.* 2007a), milk-to-plasma ratios of less than 0.5 for risperidone and less than 0.88 for paliperidone (Hill *et al.* 2000; Ilett *et al.* 2004; Weggelaar *et al.* 2011), and RIDs via lactation ranging from 2.3% to 4.7% of the maternal dose (Ilett *et al.* 2004; Weggelaar *et al.* 2011).

Aripiprazole

Prenatal use of aripiprazole, like that of quetiapine, is rising (Huybrechts *et al.* 2016; Park *et al.* 2017). Reproductive safety data for aripiprazole include findings from a large cohort study of 1,756 cases of first-trimester aripiprazole exposure, which reported no evidence of elevated risk for overall congenital or cardiac anomalies (Huybrechts *et al.* 2016). Similarly, prospective data from a national registry (*n* = 163) did not suggest an elevated risk for major malformations after aripiprazole exposure (Freeman *et al.* 2021). There has been no systematic study of neurodevelopmental outcomes following aripiprazole exposure.

Studies have raised concern about the impact of aripiprazole on obstetrical outcomes. For example, a prospective case series of 86 mother-infant dyads demonstrated an increased risk of preterm birth and fetal growth restriction but no evidence of increased risk for miscarriage, preeclampsia, or gestational diabetes (Bellet *et al.* 2015). Additionally, a retrospective case series of 26 prenatal aripiprazole exposures reported higher rates of gestational hypertension (*n* = 4) and NICU admission (*n* = 9) (Galbally *et al.* 2018). A single case report found poor respiratory effort at birth (Watanabe *et al.* 2011), but other case reports found no adverse obstetrical or neonatal outcomes (Gentile *et al.* 2011; Lutz *et al.* 2010; Windhager *et al.* 2014). In the only report of prenatal use of long-acting injectable aripiprazole, no pregnancy complications, congenital malformations, or developmental abnormalities were reported (Ballester-Gracia *et al.* 2019).

Pharmacokinetic studies found that aripiprazole's placental passage rate among four mother-infant dyads was 53.3%-54.7% (Watanabe *et al.* 2011; Windhager *et al.* 2014).

Of the three case reports of aripiprazole in lactation, the milk excretion profiles are questionable in two (Lutz *et al.* 2010; Schlotterbeck *et al.* 2007), and the other shows a 0.20 infant-to-maternal plasma ratio (Watanabe *et al.* 2011). Of note, aripiprazole has been linked with lactation failure, which may be due to its established prolactin-lowering effects (Cuomo *et al.* 2018; Komaroff 2021; Yskes *et al.* 2018).

Ziprasidone

The largest cohort study of prenatal ziprasidone exposure (*n* = 697) found no association with risk for overall or cardiac malformations (Huybrechts *et al.* 2016). Additionally, a single case report of ziprasidone exposure in utero and during breastfeeding reported normal growth and development at 6 months (Werremeyer 2009). Data concerning ziprasidone concentration in breast milk are limited to a single case that reported a milk-to-plasma ratio of 0.06 (Schlotterbeck *et al.* 2009).

Other SGAs

A case report of a single mother-infant breastfeeding dyad found a RID of 0.16% for lurasidone, with no adverse effects noted in the infant (Keightley *et al.* 2020). Otherwise, information about the perinatal use of other SGAs, including asenapine, brexpiprazole, cariprazine, iloperidone, lumateperone, and lurasidone, is scant.

First-Generation Antipsychotics

In contrast to SGAs, the first-generation antipsychotics (FGAs) have an extensive reproductive safety database addressing both somatic and neurobehavioral teratogenicity. Furthermore, the historical use of phenothiazine antipsychotics to treat nausea and vomiting of pregnancy aids in separating the effects of psychiatric illness and antipsychotic exposure on pregnancy outcome. Chlorpromazine, haloperidol, and perphenazine have received the greatest scrutiny, with no significant associations between these compounds and major malformations (Goldberg and DiMascio 1978; Hill and Stern 1979; Nurnberg and Prudic 1984). In a study of 100 women treated with haloperidol (mean dosage = 1.2 mg/day) for hyperemesis gravidarum, no differences in gestational duration, fetal viability, or birthweight were noted (Van Waes and Van de Velde 1969). In a prospective study encompassing nearly 20,000 women treated primarily with phenothiazines for emesis, Milkovich and van den Berg (1976) found no significant association with neonatal survival rates or severe anomalies. Similar results have been obtained in retrospective studies of women treated with trifluoperazine (Moriarty and Nance 1963; Rawlings *et al.* 1963). In contrast, Rumeau-Rouquette *et al.* (1977) reported a significant association of major anomalies with prenatal exposure to aliphatic phenothiazines but not piperazine-or piperidine-class agents. Reanalysis of the Milkovich and van den Berg (1976) data found a significant risk of malformations associated with phenothiazine exposure in weeks 4 through 10 of gestation (Edlund and Craig 1984). More recent data suggest that FGAs are not major teratogens (Huybrechts *et al.* 2016).

Neurobehavioral outcome studies encompassing 203 children with prenatal FGA exposure detected no significant differences in IQ scores at 4 years of age (Kris 1965; Slone *et al.* 1977), although low antipsychotic dosages were used by many women. Conversely, some laboratory animal studies (Hoffeld *et al.* 1968; Ordy *et al.* 1966; Robertson *et al.* 1980), although not all (Dallemagne and Weiss 1982), have demonstrated persistent deficits in learning and memory among offspring prenatally exposed to FGA medications.

Beyond the teratogenic potential of the FGAs lies the possibility of fetal and infant toxicities such as neuroleptic malignant syndrome (James 1988) and extrapyramidal side effects (EPS) manifested by heightened muscle tone and increased rooting and tendon reflexes persisting for several months

(Cleary 1977; Hill *et al.* 1966; O'Connor *et al.* 1981). Furthermore, prenatal exposure to FGAs has been associated with neonatal jaundice (Scokel and Jones 1962) and postnatal intestinal obstruction (Falterman and Richardson 1980).

In our study of antipsychotic placental passage, neonatal haloperidol (n = 13) concentrations were 66% of maternal concentrations (Newport *et al.* 2007a).

In lactation, chlorpromazine is the most widely studied typical antipsychotic, with 7 infants exposed to chlorpromazine during nursing exhibiting no developmental deficits at 16-month and 5-year follow-up evaluations (Kris and Carmichael 1957). However, 3 infants in another study whose mothers were prescribed both chlorpromazine and haloperidol exhibited evidence of developmental delay at 12-18 months (Yoshida *et al.* 1998b). Pharmacokinetic investigations of FGAs during lactation, including haloperidol (Stewart *et al.* 1980; Whalley *et al.* 1981; Yoshida *et al.* 1998b), trifluoperazine (Wilson *et al.* 1980; Yoshida *et al.* 1998b), perphenazine (Wilson *et al.* 1980), thioxanthenes (Matheson and Skjaeraasen 1988), and chlorpromazine (Yoshida *et al.* 1998b), have uniformly reported milk-to-plasma ratios of less than 1, although adequate control for distribution and time gradients is lacking in these studies. One group postulated that the physicochemical properties of perphenazine could lead it to become "trapped" in breast milk (Wilson *et al.* 1980); however, this speculation is unconfirmed.

Fetal and infant exposure to any of the various agents available for the management of EPS (e.g., diphenhydramine, benztropine, amantadine) also raises concern. Early reports of first-trimester diphenhydramine exposure reported elevated rates of major and minor anomalies, including elevated risk of oral clefts (Miller 1991; Saxen 1974; Wisner and Perel 1988). However, a more recent epidemiological investigation did not find an association between diphenhydramine use in early pregnancy and oral clefts (Li *et al.* 2013), and diphenhydramine is routinely used during pregnancy without issue. Clinical studies of the teratogenic potential of benztropine and amantadine are lacking, although laboratory animal studies indicate that amantadine is associated with an elevated risk of congenital malformations (Hirsch and Swartz 1980). Perinatal toxicities, including neonatal intestinal obstruction after gestational exposure to benztropine (Falterman and Richardson 1980) and a possible neonatal diphenhydramine withdrawal syndrome manifested by tremulousness and diarrhea (Parkin 1974), also warrant concern.

In summary, FGAs have been widely used for more than 60 years, and the paucity of data linking these agents to either teratogenic or toxic effects suggests that their risks are minimal. In particular, piperazine phenothiazines (e.g., trifluoperazine, perphenazine) may have especially limited teratogenic potential (Rumeau-Rouquette *et al.* 1977). FGAs used during the peripartum should be kept at the lowest effective dosage to minimize the need for adjunctive medications to manage EPS and to decrease the risk of neonatal EPS.

Anxiolytics

Benzodiazepines

A recent meta-analysis of 32 studies estimated the worldwide prevalence of benzodiazepine use during pregnancy to be 1.9% (Bais *et al.* 2020). Although the earliest benzodiazepine teratogenicity studies reported an increased risk of oral clefts after diazepam exposure (Aarskog 1975; Saxen 1975; Saxen and Saxen 1975), later studies failed to confirm this association (Ban *et al.* 2014; Entman and Vaughn 1984; Rosenberg *et al.* 1983; Shiono and Mills 1984). A subsequent meta-analysis demonstrated that prenatal benzodiazepine exposure does confer an increased risk of oral cleft, although the absolute risk increased by only 0.01% (Altshuler *et al.* 1996). This conclusion is consistent with a later case-control study finding no difference in the rate of prenatal benzodiazepine exposure between more than 38,000 infants with congenital anomalies and nearly 23,000 control subjects (Eros *et al.* 2002). Prospective studies of first-trimester alprazolam exposure encompassing approximately

1,300 pregnancies demonstrated no excess of oral clefts or other birth defects (Barry and St Clair 1987; Schick-Boschetto and Zuber 1992; St Clair and Schirmer 1992), and a study of first-trimester exposure to diazepam and temazepam echoed this finding (Ban *et al.* 2014). A large well-designed cohort study found no increased risk of congenital malformations with benzodiazepine or hypnotic benzodiazepine receptor agonists after excluding concomitant drug exposures (Wikner *et al.* 2007). A recent meta-analysis of eight prospective cohort studies reported no increased risk of major malformations with benzodiazepine exposure alone but found an increased risk of malformations with a combination of benzodiazepines and antidepressants (Grigoriadis *et al.* 2019). Data from a recent large multisite population-based case-control study suggested increased risks with prenatal benzodiazepine exposure for specific anomalies including Dandy-Walker malformation, anophthalmia and microphthalmia, esophageal atresia or stenosis, and pulmonary valve stenosis; however, given small sample sizes and wide confidence intervals, replication of these data is needed (Tinker *et al.* 2019).

Although benzodiazepine teratogenicity data are somewhat mixed, benzodiazepine neonatal syndromes are well documented. Numerous groups have described a floppy infant syndrome characterized by hypothermia, lethargy, poor respiratory effort, and feeding difficulties following benzodiazepine exposure in late pregnancy (Erkkola *et al.* 1983; Fisher *et al.* 1985; Haram 1977; Kallen and Reis 2012; Kriel and Cloyd 1982; McAuley *et al.* 1982; Sanchis *et al.* 1991; Speight 1977; Woods and Malan 1978). In a study of 53 infants, lorazepam-exposed term neonates showed no evidence of toxicity other than a brief delay in establishing feeding, whereas preterm infants and term infants whose mothers had received larger intravenous dosages of lorazepam exhibited symptoms consistent with floppy infant syndrome (Whitelaw *et al.* 1981). Neonatal withdrawal syndromes characterized by restlessness, hypertonia, hyperreflexia, tremulousness, apnea, diarrhea, and vomiting are described in infants whose mothers were taking alprazolam (Barry and St Clair 1987), chlordiazepoxide (Athinarayanan *et al.* 1976; Bitnum 1969; Stirrat *et al.* 1974), and diazepam (Backes and Cordero 1980; Mazzi 1977). More recent studies have suggested that benzodiazepine use in pregnancy may be associated with poor neonatal outcomes, including preterm delivery, low birthweight, smaller head circumference, low Apgar scores, neonatal adaptation syndrome, NICU admission, and respiratory distress; however, concomitant antidepressant use and issues of confounding complicate these findings (Calderon-Margalit *et al.* 2009; Freeman *et al.* 2018; Huitfeldt *et al.* 2020; Salisbury *et al.* 2016; Yonkers *et al.* 2017). Benzodiazepine neonatal syndromes have been reported to persist for as long as 3 months after delivery (for a review, see Miller 1991).

Pharmacokinetic studies during pregnancy indicate that benzodiazepines readily traverse the placenta and with prolonged administration may accumulate in the fetus (Mandelli *et al.* 1975; Shannon *et al.* 1972). For example, fetal concentrations of diazepam at delivery are typically higher than maternal concentrations (Erkkola *et al.* 1974). Because benzodiazepine metabolism in the fetus is slower than that in the adult, it is understandable that an agent such as diazepam, with multiple active metabolites, might accumulate in the fetus. In addition, high concentrations of diazepam are sequestered in lipophilic fetal tissues, such as the brain, lungs, and heart (Mandelli *et al.* 1975). In contrast, fetal/maternal ratios of lorazepam (which has no active metabolites) are typically less than 1 (Whitelaw *et al.* 1981). Yet neonatal clearance of lorazepam is slow, with detectable levels evident 8 days after delivery (Whitelaw *et al.* 1981), and the clearance of chlordiazepoxide appears to be even slower (Athinarayanan *et al.* 1976).

More studies to evaluate the neurobehavioral effects of prenatal benzodiazepine exposure are needed. A series of laboratory animal studies originally raised concerns that prenatal benzodiazepine exposure may produce deficits in memory and learning ability (Frieder *et al.* 1984; Hassmannova and Myslivecek 1994; Jaiswal and Bhattacharya 1993; Myslivecek *et al.* 1991). A benzodiazepine exposure syndrome--consisting of growth retardation, dysmorphism, and mental and psychomotor retardation in infants (Laegreid *et al.* 1987)--has been reported, but other investigators have disputed this finding (Winter *et al.* 1987). Some studies have found an increased risk for internalizing problems in children up to 3 years of age (Brandlistuen *et al.* 2017). However, more recent data have been reassuring, with multiple studies suggesting no adverse neurobehavioral effects with in utero benzodiazepine exposure at a variety of time points, including no differences in the incidence of behavioral abnormalities at age 8 months or in IQ scores at 4 years of age (Hartz *et al.* 1975), no correlation between antenatal exposure and language competence at age 3 years (Odsbu *et al.* 2015), no correlation with clinically relevant motor, communication, and ADHD disorders in preschoolers (Lupattelli *et al.* 2019), and no correlation with internalizing or externalizing symptoms at 5 and 6 years of age (Sundbakk *et al.* 2019; Radojcic *et al.* 2017).

Buist *et al.* (1990) concluded that benzodiazepines at low dosages present no contraindication to nursing. A retrospective cohort study found a sedation rate of 1.6% in infants exposed to benzodiazepines while breastfeeding, but there was no association with dosage (Kelly *et al.* 2012). However, infants with impaired metabolic capacity may exhibit sedation and poor feeding even with low maternal dosages (Wesson *et al.* 1985). Overall, benzodiazepines exhibit lower milk-to-plasma ratios than other classes of psychotropics. For example, Wretlind (1987) found a milk-to-plasma ratio of 0.1-0.3 for oxazepam and calculated that the infant daily dose via lactation is 1/1,000 of the maternal dose. The percentage of the maternal dose of lorazepam to which a nursing infant is exposed has been estimated to be 2.2% (Summerfield and Nielsen 1985). A recent study by Nishimura *et al.* (2021) found the RID for multiple benzodiazepines, including clonazepam, alprazolam, and lorazepam, to be less than 10%, with no report of adverse effects.

In summary, benzodiazepines do not appear to carry a significant risk of somatic teratogenesis, but neurobehavioral sequelae remain obscure. Because benzodiazepines are associated with neonatal risks, they should be used judiciously and tapered before delivery if possible. Benzodiazepines should not be abruptly withdrawn during pregnancy. Because lorazepam and oxazepam are less dependent on hepatic metabolism, they theoretically have less potential for fetal accumulation during pregnancy. Finally, benzodiazepines can be safely administered, in judicious dosages, during lactation. Consideration should be given to those with shorter half-lives (lorazepam) and lower lipid solubility (oxazepam) when possible. Breastfeeding should be discontinued if an infant exhibits sedation or other signs of benzodiazepine toxicity.

Buspirone

Buspirone has garnered a unique, and arguably illogical, position within the psychotropic armamentarium. Although reassuring results from animal studies led to a favorable FDA pregnancy designation for buspirone, published clinical data are limited to a single report of prenatal administration of buspirone ($n = 14$) identifying one infant born with a major malformation (Wilton *et al.* 1998). There are no published reports regarding buspirone during lactation.

Hydroxyzine

The antihistamine hydroxyzine is often used as an off-label as-needed treatment for anxiety, despite evidence challenging its efficacy when used in this manner (Papadopoulos *et al.* 2010). A cohort study examining various outcomes associated with hydroxyzine ($n = 53$) found no evidence linking it to major malformations, low birthweight, preterm birth, or neonatal distress (Einarson *et al.* 1997). However, a review of the French Pharmacovigilance Database discovered that hydroxyzine was the third most frequently cited medication associated with adverse effects in breastfeeding infants; complications included sedation, malaise, bradycardia, cyanosis, and constipation (Soussan *et al.* 2014). There are no reports regarding hydroxyzine's reproductive pharmacokinetics or neurodevelopmental consequences of exposure.

Psychostimulants

Methylphenidate and Amphetamines

The prevalence of ADHD among adult women is 3.2% (Kessler *et al.* 2006), and psychostimulants are the gold standard for treatment. Unfortunately, the reproductive safety data for these medications remain sparse. While there is compelling evidence that prenatal methamphetamine abuse conveys an increased risk of preeclampsia and hypertension, fetal demise, preterm delivery, and intrauterine growth restriction, not to mention the potential for long-term neurological, developmental, and behavioral problems in the baby (Dinger *et al.* 2017), it is problematic to draw inferences from methamphetamine abuse outcomes and apply them to therapeutic psychostimulant use, because illicit misuse is likely to involve much higher dosages than prescribed medication, and abuse of stimulants is also accompanied by use of other addictive substances, such as tobacco, alcohol, and other drugs, which can cloud the origin of a negative outcome (Debooy *et al.* 1993).

To date, the data regarding therapeutic use of psychostimulants during pregnancy, albeit limited, have been reassuring. Stimulants at prescribed dosages do not appear to show any increased risk of malformations (Diav-Citrin *et al.* 2016; Pottegard *et al.* 2014). Although one study showed a slightly higher rate of cardiac malformations, the difference was not statistically significant (Huybrechts *et al.* 2018). There are no systematic studies examining neurodevelopmental outcomes following prenatal psychostimulant therapy.

A Swedish study comparing nearly 1,600 stimulant-exposed babies with approximately 9,500 babies of women with untreated ADHD found slightly higher risks of preterm birth and NICU stay in association with psychostimulant therapy; however, this study found no differences in congenital malformations, Apgar scores, or neonatal withdrawal symptoms (Norby *et al.* 2017). In addition, a nested case-control study reported an increased risk for gestational hypertension (OR = 6.11) among women treated with psychostimulants; in the subgroup receiving stimulant therapy, those with gestational hypertension had higher daily stimulant dosages than those without hypertension (33.8 mg vs. 11.9 mg) (Newport *et al.* 2016).

Psychostimulants are not contraindicated in lactation. Reports have shown drug levels to be low or nondetectable in breast milk (Marchese *et al.* 2015; Ornoy 2018). Among the medications for which data are available, the RID is consistently below 10%, with methylphenidate-derived medications having lower RIDs than amphetamine-derived ones

(Hale 2021). In one study of 103 babies exposed to psychostimulants in breast milk, no adverse effects on the babies were noted (Ayd 1973). However, by virtue of their dopaminergic mechanism of action, and, in turn, dopamine's inhibitory impact on prolactin activity, stimulants can theoretically interfere with breast milk production, particularly at higher dosages (Drugs and Lactation Database 2023a). However, some studies have failed to find a statistically significant effect, and clinical experience varies among physicians.

Atomoxetine

While psychostimulant medications are generally the first-line choice for treatment of ADHD, there are also nonstimulant options, including atomoxetine, an SNRI. Few data are available on atomoxetine, but so far no risk for malformations or adverse pregnancy outcomes has been noted (J. M. Cohen *et al.* 2017). There are no published data on the neurodevelopmental effect of atomoxetine or the safety of atomoxetine in breastfeeding, but two case reports showed no complications in the infants (Drugs and Lactation Database 2023b).

Modafinil and Armodafinil

While they do not hold FDA indications for ADHD, the psychostimulants modafinil and armodafinil are sometimes used off-label for ADHD. Their reproductive safety data are scant and mixed thus far. In 2020, two small studies with sample sizes of 49 and 102, respectively, showed increased risk (12%-13%) of congenital malformations including hypospadias, torticollis, and heart defects (Damkier and Broe 2020; Kaplan *et al.* 2021), yet later that year a larger study of 133 exposed pregnancies showed no increased risk (Cesta *et al.* 2020). With so little information, we need to remain cautious about the use of these medications in pregnancy. The breastfeeding data are also very limited, with just one formal case report of a RID of 5.3% for a nursing mother receiving 250 mg of modafinil daily for hypersomnia (Aurora *et al.* 2018).

Anti-Addiction Medications

Substance use disorders convey a host of risks during pregnancy and the postpartum period. With the emergence of medication-assisted treatment (MAT) to aid the recovery

of those addicted to certain substances, particularly opioids, alcohol, and tobacco, using anti-addiction medicines during pregnancy warrants careful consideration. The risks of such agents must be weighed against the well-documented risks of continued substance abuse. For example, opioid abuse during pregnancy carries myriad risks including repeated episodes of fetal withdrawal, fetal seizures, diminished fetal growth, preterm birth, and fetal death (National Institute on Drug Abuse 2017). Approximately 10% of American women continue to consume alcohol during pregnancy, with roughly one-third of these binge drinking (Tan *et al.* 2015). Prenatal alcohol abuse is associated with a heightened risk of miscarriage, stillbirth, preterm birth, sudden infant death syndrome, and fetal alcohol spectrum disorder (National Institute on Alcohol Abuse and Alcoholism 2021). Tobacco use during pregnancy is linked to increased risk for miscarriage, stillbirth, preterm birth, low birthweight, and childhood asthma and vision problems (National Institute on Drug Abuse 2020).

Medications for Opioid Use Disorder

Opioid Agonists

MAT has emerged as the standard of care for opioid use disorder for all adults, including pregnant women. Opioid detoxification during pregnancy is not recommended because of high relapse rates coupled with the poor outcomes noted above among women who continue to abuse opioids. MAT for opioid abuse may consist of treatment with an opioid agonist, methadone or buprenorphine, or a long-acting injectable opioid antagonist, naltrexone.

Opioid-addicted pregnant women receiving methadone or buprenorphine MAT are more likely to engage in prenatal care and have reduced infection risk, normal fetal growth, and lower fetal and neonatal mortality than those without MAT (Jones *et al.* 2008; Zhao *et al.* 2020). Although a consensus has emerged that prenatal MAT is far safer than continued opioid abuse, it is not without risks. Several studies, though not all (Zedler *et al.* 2016), have reported higher malformation rates among methadone-exposed children, including a population-based study of overall malformation rates (OR = 2.05) (Wurst *et al.* 2016); a case-control study finding a higher risk for Pierre Robin sequence (OR = 12.3), a rare craniofacial anomaly, and cleft palate (OR = 5.0) (Cleary *et al.* 2020); and another reporting a higher malformation rate than among children exposed to naltrexone and buprenorphine (Kelty and Hulse 2017a). To date, studies have not demonstrated an association between prenatal buprenorphine exposure and risk for major malformations (Kelty and Hulse 2017b; Wurst *et al.* 2016; Zedler *et al.* 2016).

While there are obstetrical and newborn risks associated with any opioid agonist therapy, such as preterm birth, low birthweight, and neonatal opioid withdrawal syndrome (NOWS), continued opioid abuse leads to more frequent and more severe poor outcomes (Minozzi *et al.* 2020; Mozurkewich and Rayburn 2014; Tran *et al.* 2017). As mentioned, NOWS is an expected adverse outcome with opioid agonist therapy proximate to delivery. For example, the landmark Maternal Opioid Treatment: Human Experimental Research randomized clinical trial showed a similar incidence of NOWS among newborns of buprenorphine-and methadone-maintained mothers (Jones *et al.* 2010); however, although pregnant women receiving buprenorphine MAT were twice as likely to screen positive for continued illicit opioid use at delivery as those receiving methadone MAT (11.1% vs. 5.6%) (Kaltenbach *et al.* 2012), the severity of NOWS was markedly lower among infants exposed to buprenorphine than those exposed to methadone, resulting in a shorter duration of NOWS treatment (4.1 days vs. 9.9 days), a shorter hospital stay (10 days vs. 17.5 days), and a lower morphine requirement for neonatal detoxification (mean dosage 1.1 mg vs 10.4 mg) (Jones *et al.* 2010). Moreover, methadone, but not buprenorphine, has been associated with neonatal QTc prolongation and arrhythmias (Hussain and Ewer 2007; Parikh *et al.* 2011).

Serial assessments of cognitive and language development, temperament, and sensory processing through 3 years of age conducted by the Maternal Opioid Treatment: Human Experimental Research study (Kaltenbach *et al.* 2018) demonstrated no deleterious effect of prenatal MAT with methadone or buprenorphine.

The American College of Obstetricians and Gynecologists encourages new mothers who are stable on opioid agonist therapy and abstinent from illicit opioid use to breastfeed in the absence of other contraindications such as maternal HIV infection (American College of Obstetricians and Gynecologists 2017). A study of seven breastfeeding infants demonstrated no adverse effects of buprenorphine exposure, with median milk/plasma ratios of 1.7 and 0.7 and RIDs of 0.2% and 0.12% for buprenorphine and its active metabolite norbuprenorphine, respectively (Lindemalm *et al.* 2009). A methadone lactation study ($n = 20$) revealed a mean milk/plasma ratio of 0.40 and a RID of 2.1% (Bogen *et al.* 2011).

A systematic review of eight studies examining NOWS concluded that breastfeeding reduced the severity and duration of NOWS for infants of women receiving methadone but not buprenorphine MAT (McQueen *et al.* 2019). However, in light of methadone's low RID via lactation, it seems unlikely that extending methadone exposure during breastfeeding alone explains the attenuation of NOWS. It has been suggested that this may instead be a consequence of physical contact between mother and newborn when breastfeeding, as well as maternal engagement in care (Saia *et al.* 2016).

Of note, one key advantage for buprenorphine over methadone is its accessibility. Methadone maintenance requires clinic attendance 6 or 7 days per week, and take-home doses are seldom permitted. The difficulties this produces for pregnant and postpartum women has led one group to recommend greater flexibility in methadone maintenance delivery for pregnant and postpartum women (McCarthy *et al.* 2021).

Opioid Antagonists

Introduced for the treatment of opioid use disorders as a long-acting injectable formulation, the opioid antagonist naltrexone later garnered an FDA indication as an oral formulation for the treatment of alcohol use disorder. Because of its limited reproductive safety data relative to methadone and buprenorphine, naltrexone is less preferred for managing opioid abuse during pregnancy (Ecker *et al.* 2019). A cohort study comparing 121 naltrexone-treated and 109 methadone-or buprenorphine-treated pregnant women observed no difference in rates of congenital malformation (Towers *et al.* 2020). To date, there are no clinical studies examining the neurodevelopmental sequelae of prenatal naltrexone exposure.

Although some have expressed concern about the risk of fetal abstinence syndrome during the initiation of prenatal naltrexone treatment and the risk for opioid relapse during the required 7-10 days of opioid abstinence following detoxification (Kelty and Hulse 2017a; Minozzi *et al.* 2011), these concerns were not realized in a recent prospective study (Towers *et al.* 2020). Conversely, two studies indicate that prenatal MAT with naltrexone, in comparison to the opioid agonists, carries a significantly lower risk of NOWS and shorter length of hospitalization (Towers *et al.* 2020; Wachman *et al.* 2019).

The lone in vivo study of naltrexone placental passage ($n = 20$) observed mean umbilical cord/maternal plasma ratios of 74% and 92%, respectively, for naltrexone and its active metabolite 6-b-naltrexol (Towers *et al.* 2020). Naltrexone therapy proximate to delivery poses a challenge for postdelivery pain management (Jones and Terplan 2018). However, both maternal and fetal concentrations were undetectable at delivery when oral naltrexone had been discontinued at least 60 hours before delivery (Towers *et al.* 2020), suggesting that postdelivery pain management concerns can be remedied by discontinuing naltrexone therapy as little as 3 days before delivery. If the long-acting injectable is continued during pregnancy, it is recommended to transition to the oral formulation at least 1 month before the expected delivery.

Naltrexone use during breastfeeding is limited to one case report, where the total RID (naltrexone + 6-b-naltrexol) was estimated to be 1.06% (Chan *et al.* 2004).

The other commercially available opioid antagonist, naloxone, is administered parenterally as an antidote for opioid overdose. Little guidance is available on naloxone use during gestation. A general recommendation for any patient who has overdosed on an opioid is to administer naloxone when the respiratory rate drops to 12 or below (Blandthorn *et al.* 2018). To minimize the potential for maternal and fetal opioid withdrawal after naloxone administration, treatment should be initiated with the lowest dosage of naloxone and accompanied by medical care to monitor both the mother and fetus (Blandthorn *et al.* 2018).

Medications for Alcohol Use Disorder

Medications available for the management of alcohol use disorder include naltrexone, acamprosate, disulfiram, and two additional medications approved for use in Europe, nalmefene and gamma-hydroxybutyrate. Reproductive safety data for all these agents remains sparse; consequently, their use during pregnancy, despite the attendant risks of prenatal alcohol abuse, is not routinely encouraged (Reus *et al.* 2018; Rolland *et al.* 2016; Thibaut *et al.* 2019). Some guidelines suggest that first-line maintenance agents for alcoholism (i.e., naltrexone or acamprosate) be considered on a case-by-case basis for women who are stable on the medication before conception (Reus *et al.* 2018; Rolland *et al.* 2016).

Acamprosate

The reproductive safety data for naltrexone were reviewed earlier (see "Opioid Antagonists" in the "Medications for Opioid Use Disorder" section). Acamprosate's reproductive safety data are limited to a single retrospective cohort study (Kelty *et al.* 2019) reporting that prenatal acamprosate (n = 54) exposure was not associated with heightened risk for congenital malformations, low birthweight, or neonatal complications. There are no acamprosate studies examining the neurodevelopmental effects of prenatal exposure or its safety profile in lactation.

Disulfiram

The extant reproductive safety literature for disulfiram encompasses 38 cases, of which 11 (28.9%) reported a major malformation; however, many of the fetuses were also exposed to alcohol and other potentially causative substances (Kelty *et al.* 2021). Theoretical concerns about the impact of the "Antabuse reaction" on the fetus led the French Alcohol Society guideline to recommend discontinuing disulfiram therapy during pregnancy even if the patient is stabilized on it before conception (Rolland *et al.* 2016).

Medications for Smoking Cessation

Pregnancy often serves as a motivating factor for smoking cessation; however, many women may need pharmacological assistance (American College of Obstetricians and Gynecologists 2020; Myung *et al.* 2012). The mainstays of smoking cessation pharmacotherapies in the United States include bupropion, varenicline, and nicotine replacement therapy (NRT). Although it has been challenging to distinguish the effects of NRT from those of continued smoking, NRT products are not thought to be major teratogens; however, evidence for other perinatal outcomes is inconclusive (Blanc *et al.* 2021; Taylor *et al.* 2021). Two recent systematic reviews (Patnode *et al.* 2021; Taylor *et al.* 2021) did not find a relationship between NRT and either positive or adverse perinatal outcomes. Another systematic review (Blanc *et al.* 2021) reported an association between NRT during pregnancy and infant colic at 6 months and risk of ADHD at age 7 years, with ORs similar to those with continued tobacco use. Similarly, rates of stillbirth, adverse birth outcomes, or congenital malformations following prenatal exposure to NRT, bupropion, or varenicline did not differ from those among infants whose mothers continued to smoke but were unexposed to these medications (Patnode *et al.* 2021). In a recent meta-analysis, bupropion, used as a smoking cessation aid, did not have any positive or negative effects on rates of major malformations, birthweight, or premature birth (Turner *et al.* 2019). Data are sparse for varenicline use in pregnancy, but the limited available data do not suggest it is a major teratogen (Turner *et al.* 2019). Despite the limited and sometimes conflicting safety data regarding the use of NRT, bupropion, or varenicline during pregnancy, the American College of Obstetricians and Gynecologists still recommends offering them as possible smoking cessation aids (American College of Obstetricians and Gynecologists 2020).

Unfortunately, more than half of women who abstain from using tobacco during pregnancy resume smoking within 6-12 months postpartum (American College of Obstetricians and Gynecologists 2020; Napierala *et al.* 2016). Data are limited regarding the risks of NRT during lactation, but it is well known that nicotine passes freely into breast milk. In a study of 15 lactating women smoking an average of 17 cigarettes a day, the nicotine levels for the 21 mg patch were similar to their levels when smoking but declined by almost 70% with the 7 mg patch (Ilett *et al.* 2003). The authors estimated that the RID of the nicotine patches was approximately 1.9% (Ilett *et al.* 2003). There are no known studies with other NRT formulations, such as lozenges or gum. Maternal smoking has been associated with decreased milk production and elevated risk of sudden infant death syndrome, with nicotine itself being the suspected cause (Taylor *et al.* 2021). This implies that NRT products may have similar risks, although data supporting this theory are lacking. Data for bupropion during lactation are limited, but reported concentrations are low and unlikely to result in negative outcomes. The use of varenicline during lactation is not currently recommended because of the lack of published data (American College of Obstetricians and Gynecologists 2020).

Hypnotics

Insomnia commonly co-occurs with various mental disorders during pregnancy and the postpartum period; moreover, the severity of prenatal depression and anxiety is associated with the frequency of hypnotic use during gestation (Newport *et al.* 2012). Consequently, the safety of hypnotic pharmacotherapy warrants discussion. Pharmacotherapy alternatives for insomnia include benzodiazepines (discussed previously), benzodiazepine receptor agonists, antihistamine hypnotics, melatonin receptor agonists, and "natural" hypnotics.

Benzodiazepine Receptor Agonists

The benzodiazepine receptor agonists, including zolpidem, zaleplon, and zopiclone and its enantiomer eszopiclone, have been widely used during pregnancy despite limited reproductive safety data. Although these limited data do not provide evidence, as yet, for increasing risk for congenital malformations, these medications have been associated with neonatal withdrawal (Ban *et al.* 2014; Wikner *et al.* 2007; Wilton *et al.* 1998).

Zolpidem crosses the placenta but rapidly clears the fetal circulation (Askew 2007; Juric *et al.* 2009). Small preliminary studies are not indicative of malformation risk (Juric *et al.* 2009; Wang *et al.* 2010), although one study reported a small increase in the risk for gastrointestinal tract malformations (Wikner and Kallen 2011). Data on the risk of preterm delivery and low birthweight associated with zolpidem use are mixed (Juric *et al.* 2009; Wang *et al.* 2010; Wikner *et al.* 2007). Limited data on zaleplon (n = 32) found no evidence of increased risk of malformations (Wikner and Kallen 2011). Two studies reported no increased rate of malformations or low birthweight with zopiclone (Diav-Citrin *et al.* 1999; Stephens *et al.* 2008). There are no published reports regarding the safety profile or pharmacokinetics of eszopiclone exposure during gestation.

The RID in maternal breast milk is 0.4% for zaleplon, 0.02%-0.18% for zolpidem, and 1.5% for zopiclone (Hale 2021). There are no published reports regarding eszopiclone during lactation, although its breast milk excretion rate and safety profile are presumably akin to those of the racemic mixture, zopiclone.

Antihistaminic Hypnotics

Diphenhydramine and Doxylamine

Meta-analyses have not found an association between first-generation antihistamines (e.g., diphenhydramine and doxylamine) as a class and malformation risk (McKeigue *et al.* 1994; Seto *et al.* 1997). The majority of available safety data come from two large case-control studies. An initial analysis of the National Birth Defects Prevention Study reported weak to moderate associations between diphenhydramine and doxylamine exposure and isolated noncardiac malformations (Gilboa *et al.* 2009); however, a subsequent analysis of the same data found no increase in risk for congenital malformations with these agents (Anderka *et al.* 2012). An analysis of the Slone Epidemiology Center Birth Defects Study found no increased risk of congenital malformations with diphenhydramine or doxylamine exposure (Li *et al.* 2013). One randomized controlled trial found diphenhydramine to be efficacious for insomnia in pregnancy (Khazaie *et al.* 2013).

Trazodone

Trazodone is a phenylpiperazine antidepressant most often used as a sleep aid because of its sedating properties. Literature on trazodone in pregnancy is limited. Two prospective controlled studies did not find an increased risk of congenital malformations (Einarson *et al.* 2003, 2009). Cord blood levels are equivalent to maternal serum levels (Saito *et al.* 2021). One study of excretion of trazodone into breast milk suggests low transmission, with infants receiving 0.6% of the maternal dose (Verbeeck *et al.* 1986). One randomized controlled trial found trazodone efficacious for insomnia in pregnancy, with increased sleep duration and efficiency (Khazaie *et al.* 2013).

Tricyclic Antidepressants

The potent antihistamines amitriptyline and nortriptyline are TCAs that may be used in the treatment of insomnia in pregnancy, in addition to depression and migraine prophylaxis. Earlier concerns regarding limb anomalies were not confirmed in subsequent studies (Altshuler *et al.* 1996; Vasilakis-Scaramozza *et al.* 2013), and neurodevelopmental data are generally reassuring (Nulman *et al.* 2002). Limited data on neonatal impacts at delivery suggest increased risk for tachycardia and withdrawal (Misri and

Sivertz 1991; ter Horst *et al.* 2012). The RID of amitriptyline in maternal milk has been estimated as 1.08%-2.8%, with one report of severe sedation and poor feeding in an exposed infant (Hale 2021; Uguz 2017). The RID of nortriptyline is 1.7%-3.36%, and there have been no reported infant concerns (Hale 2021).

Quetiapine

Quetiapine is an SGA that is often used at lower dosages as an off-label treatment for insomnia in pregnancy, given its sedative properties and favorable reproductive safety profile. Its safety profile was reviewed earlier in this chapter (see "Quetiapine" under "Second-Generation Antipsychotics").

Melatonin Receptor Agonists

Melatonin is a neuroendocrine hormone secreted by the pineal gland, which regulates multiple biological systems, including circadian rhythm, the endocrine system, and the immune system. Maternal melatonin crosses the placenta and enters the fetal circulation freely, where it regulates fetal circadian rhythm and reproductive development (Davis 1997). Although studies suggest that endogenous melatonin is essential for pregnancy, and perhaps even protective against preeclampsia and miscarriage (Tamura *et al.* 2008), there are no published reports of the safety of exogenous melatonin supplementation in pregnancy. Conflicting data from animal studies suggest possible risks of melatonin supplementation, including decreased birthweight, increased mortality, and effects on reproductive development (Colmenero *et al.* 1991; Gonzalez-Candia *et al.* 2016; Singh *et al.* 2012), contrasting possible neuroprotective benefits (Dominguez Rubio *et al.* 2017). Limited published data on endogenous melatonin levels in maternal breast milk suggest that the amount of melatonin in milk ranges from 35%-80% of maternal plasma levels (Illnerova *et al.* 1993), and there are no available data on levels of exogenous melatonin in maternal breast milk (Hale

2021). Melatonin supplementation is discouraged during pregnancy and lactation, given the concerning animal data, lack of human evidence, and theoretical risks.

Agomelatine is a melatonin receptor agonist that is available in Europe but not the United States. There are no published reports on the use of agomelatine in pregnancy; however, there are two case reports on its use in lactation, suggesting low levels in maternal breast milk and limited risk of exposure to the infant due to the short half-life (Schmidt *et al.* 2013; Xiao 2021).

There are no published reports on the use of melatonin receptor agonists ramelteon and tasimelteon in pregnancy or lactation.

Orexin Antagonists

The recently introduced orexin antagonists are a distinct class of hypnotic agents. Three orexin antagonists, daridorexant, lemborexant, and suvorexant, are currently approved for use in the United States. There are no published reports on the use of these agents during pregnancy or lactation.

Natural Hypnotics

Natural agents frequently used to treat insomnia include GABA, glycine, lavender, passionflower, L-theanine, L-tryptophan, magnesium, and valerian root. Most of these agents have no published reproductive safety data for pregnancy or lactation.

While there are no published reports on the use of lavender in pregnancy or lactation, its use for pain control during labor demonstrated significant therapeutic effects for the mother, with no evident adverse neonatal effects (Yazdkhasti and Pirak 2016). There are no published reports on the use of GABA in human pregnancy or lactation; however, animal data suggest that early pregnancy exposure to GABA may impair endometrial receptivity and embryo development in rats (Tian *et al.* 2020).

Passionflower (*Passiflora incarnata*), an herbal supplement used for anxiety and insomnia, has been associated with neonatal death, premature rupture of membranes, meconium aspiration, and persistent pulmonary hypertension of the newborn in one case report series (Ozturk and Kalayci 2018).

The reproductive safety of L-tryptophan, an amino acid used for depression and insomnia, has received limited scrutiny. One study reported a significant decrease in fetal breathing movements associated with tryptophan exposure (Devoe *et al.* 1986). There are no published data on L-tryptophan in lactation; however, given the high dosages needed, high maternal plasma levels, and frequent report of adverse effects, use in lactation cannot be recommended (Pizzorno and Murray 2020).

Magnesium is an essential mineral often taken as an oral dietary supplement for leg cramps, anxiety, and insomnia. Guidelines produced by the Institutes of Medicine suggest daily dosages below the upper limit of 350 mg daily (Institute of Medicine Standing Committee on the Scientific Evaluation of Dietary Reference Intakes 1997). It has also been examined for benefit in the context of a variety of maternal and neonatal obstetrical outcomes; however, a systematic review found no high-quality evidence to support magnesium oral supplementation in pregnancy (Makrides *et al.* 2014). The authors found no significant difference in primary outcomes of perinatal mortality, small-for-gestational-age status, maternal mortality, and preeclampsia. They attributed a slightly increased risk of neonatal death in the supplemented group to a series of anomalous severe congenital abnormalities.

Conclusion: Clinical Decision-Making During the Perinatal Period

When managing psychiatric illness during pregnancy or breastfeeding, simply ingesting the minutiae of the reproductive safety literature pertinent to each medication is insufficient for providing optimal care. Although this fund of knowledge is necessary, it must be interfaced with a sound framework for choosing between the various available treatment alternatives. Fundamental to this process is recognizing that the selection must consider the risks to mother, unborn child, and even older children attributable to the illness and weigh those against risks posed by psychotropic exposure. Ultimately, no risk-free alternative exists other than choosing not to conceive. Thus, there are numerous overarching concerns to be confronted when any pharmacotherapy is under consideration. These concerns form the basis for delineating general principles to guide perinatal psychiatric treatment planning, which are perhaps best conveyed through a series of questions commonly encountered during the decision-making process.

Is It Safe to Take This Medication While Pregnant (or Breastfeeding)?

Patients, and many clinicians, often try to limit the risk assessment to this sole question, seeking an answer devoid of ambiguity. However, any decision predicated solely on this question is wholly inadequate. First, this question ignores the risk posed by the illness. Second, there is no psychotropic medication for which all potential risks have been exhaustively examined and dismissed. Consequently, no psychotropic can be categorically deemed safe during pregnancy or lactation. Third, posed in this manner, the question inexorably leads to an assumption that maternal well-being is always in direct competition with fetal well-being. This so-called fetal-maternal conflict should be avoided, as it is a sure path to self-recrimination for any expectant mother faced with the challenges posed by perinatal mental illness.

As no psychotropic can be guaranteed as being safe during pregnancy, this question must be reframed so that it does not place the expectant mother's best interests in conflict with her baby's. A better question is, "Is it safest to take this medication, another medication, or no medication at all while pregnant (or breastfeeding)?" This more appropriate question, however, invites a series of additional questions.

What Risk Does This Illness Pose to the Mother and Her Child?

This question is not unique to mental illness. It is encountered whenever a pregnant or nursing mother has any illness that may necessitate pharmacotherapy. Understanding the risk associated with a mother's illness is the starting point in identifying the appropriate course of treatment. If an illness poses little risk to mother and child (e.g., allergic rhinitis), then only minimal pharmacological risk can be justified. However, medications carrying significant risk may be acceptable and even preferable if they provide protection from an illness that poses great risk to mother or child (e.g., epilepsy, HIV).

There are rapidly growing data regarding the deleterious impact of psychiatric illness during pregnancy and the postpartum period. It is now well established that moderate to severe depression and anxiety, as well as manic and psychotic syndromes, jeopardize the well-being of both mother and child, carrying short-term and long-term implications for child health and development. The same holds true for perinatal substance use disorders. However, the data are less clear for some psychiatric disorders. For example, there is no compelling evidence to indicate that maternal attention-deficit disorder, left untreated, puts mother or child at immediate risk; however, it may do so indirectly. Specifically, if suspending attention-deficit disorder treatment leaves a pregnant or postpartum patient feeling overwhelmed by her inability to cope with the demands of her day-to-day responsibilities, she may be more susceptible to worsening depression and anxiety, which would pose risk.

How Likely Is This Illness to Recur or Worsen Without Pharmacotherapy?

Ideally, an expectant mother would be able to remain well despite stopping psychotropic treatment, sparing mother and child the risks attributable to both illness and pharmacological exposure. It was once believed that pregnancy was a time of emotional well-being that conferred protection from mental illness; however, research in recent decades indicates this is not the case. Women with preexisting histories of mood, anxiety, or psychotic disorders who discontinue psychotropic treatment at conception are highly vulnerable to a recurrence of illness during pregnancy. Unfortunately, existing research has not yet made it possible to reliably identify, in advance, the small subset of women who will remain well during pregnancy after discontinuing psychiatric medication.

Clinicians may also consider the individual patient's prior course of psychiatric illness when trying to determine whether an interruption in psychotropic treatment is advisable. Pertinent questions include: How many previous episodes of illness has she experienced? How severe were the prior episodes? Were psychotic symptoms present? Has she previously had a period of sustained euthymia after stopping psychiatric medication? Did previous recurrences arise gradually or abruptly? With resumption of treatment, how quickly does the illness resolve? And finally, has she experienced a recurrence or worsening of her illness during or after a previous pregnancy?

Can This Illness Be Successfully Treated Without Medication?

Bipolar disorder and schizophrenia, by definition, require psychotropic pharmacotherapy for effective management. However, many other psychiatric illnesses (e.g., depression and anxiety disorders) can be managed effectively with evidence-based psychotherapy for some patients in the absence of psychotropic medication. Again, reviewing the patient's past psychiatric history, specifically her motivation for and past benefit derived from psychotherapy, can offer insight into the potential effectiveness of a psychotherapy-alone treatment plan. If the patient presents for a preconception evaluation having never previously received psychotherapy, she can be asked to

postpone conception long enough to engage in psychotherapy and then determine whether she can successfully discontinue psychotropic treatment. In any event, in light of its synergistic benefits, psychotherapy should be routinely recommended even to those for whom medication must be continued.

Complementary interventions of low risk, such as daily exercise, prenatal yoga, and meditation, although not "treatments" for mental disorders per se, may contribute to an overall sense of well-being and can be considered. However, naturopathic supplements (e.g., St. John's wort, *Rhodiola rosea*, saffron, lavender, maharishi amrit kalash, mentat) are not recommended during pregnancy because they are not subject to FDA scrutiny, and reproductive safety data are sparse. Pregnant and breastfeeding women should be reminded that just because a substance is produced in nature does not mean that it is safe to expose a fetus or breastfeeding infant to it.

Which Medication(s) Should Be Chosen?

Pregnancy and lactation are not times to experiment with novel treatments; thus, choosing the best medication from the outset is critical. The ideal medication balances safety and efficacy. All too often, understandably preoccupied with the safety profiles of available medications, clinicians lose sight of the need for an efficacious treatment, ill-advisedly switching to an ineffective medication simply because they understand it to be "safer." If the rationale for administering a medication during pregnancy (or breastfeeding) is to protect mother and child from an illness, then a medication is advisable only if there is a reasonable expectation of protective benefit.

For ethical reasons, clinical trials to determine psychotropic efficacy are rarely, if ever, conducted during pregnancy and breastfeeding. Only a handful of observational studies have explored this question. Thus, the best available means to determine the likely efficacy of a given medication for a particular patient is to review her treatment history. Even a medication with a favorable reproductive safety profile is difficult to justify if a previous adequate trial of it has failed for the patient. Obtaining a comprehensive treatment history documenting the efficacy, tolerability, dosage, and treatment duration for each agent is instrumental in narrowing the list of viable medication choices. Particularly important is the utility of a medication during or immediately after a previous pregnancy.

After medications with a reasonable likelihood of efficacy have been identified, safety considerations enter the decision-making process. It is important to review the reproductive safety profiles of agents deemed likely to provide therapeutic efficacy, taking into consideration the gestational timing when the decision is being made. The ideal medication regimen lies at the intersection of the efficacy and safety survey. If multiple agents remain under consideration, then the choice can be further refined in terms of potential tolerability during gestation. The scope of tolerability includes selecting agents that are less likely to contribute to pregnancy-related conditions such as gestational diabetes and gestational hypertension.

Is It Better to Reduce Medication Dosages When Pregnant or Breastfeeding?

Prescribing the minimal effective dosage is especially important during pregnancy and lactation. Upon learning that a patient is pregnant, clinicians and patients often instinctively

lower psychotropic dosages in an effort to reduce fetal exposure, but indiscriminate dosage reduction may increase the vulnerability to relapse. If the therapeutic objective is to eliminate the child's exposure to maternal illness while minimizing the child's psychotropic exposure, then perinatal dosage management must be informed by an understanding of the factors governing the alterations in drug disposition across gestation and through the placental passage and excretion into breast milk.

Dosage adjustments may be necessary to maintain a medication's efficacy during pregnancy. For example, it may be necessary to increase the dosage of TCAs to approximately 1.6 times the preconception dosage to maintain therapeutic concentrations in late pregnancy (Altshuler *et al.* 1996; Wisner *et al.* 1993). Small studies investigating SSRIs have demonstrated clearance changes across pregnancy and dosage adjustments in response to increasing maternal symptoms (Hostetter *et al.* 2000; Freeman *et al.* 2008; Sit *et al.* 2008). However, the pattern of dosage adjustment needed during gestation is not uniform for all medications. For example, among anticonvulsant and mood-stabilizing medications, serum concentrations of lamotrigine (Ohman *et al.* 2000; Pennell *et al.* 2004; Polepally *et al.* 2014; Tran *et al.* 2002) and valproate (Otani 1985; Philbert *et al.* 1985) decline steadily across gestation, whereas carbamazepine concentrations (Bardy *et* *al.* 1982b; Battino *et al.* 1982; Bologa *et al.* 1991; Dam *et al.* 1979; Lander *et al.* 1981; Omtzigt *et al.* 1993; Otani 1985; Tomson *et al.* 1994; Yerby *et al.* 1985) exhibit smaller changes that are primarily evident only in late pregnancy. These alterations in drug concentrations and dosing requirements are probably a consequence of the impact of the physiological changes of pregnancy on the pharmacokinetics (Boobis and Lewis 1983; Frederiksen 2001; Little 1999; Wyska and Jusko 2001) and possibly the pharmacodynamics (Wyska and Jusko 2001) of psychotropic medications. Ultimately, an improved understanding of the factors governing perinatal pharmacokinetic and pharmacodynamic alterations may enable the construction of personalized dosing strategies during gestation.

The level of fetal psychotropic exposure is another key consideration. All psychotropics studied to date cross the human placenta, yet there are significant differences in placental passage rates. Bidirectional placental transfer is mediated primarily by simple diffusion, and determinants of the transplacental diffusion rate include molecular weight, lipid solubility, degree of ionization, and protein-binding affinity (Audus 1999; Moore *et al.* 1966; Pacifici and Nottoli 1995). In addition, placental P-glycoprotein, which actively transports substrates from the fetal to the maternal circulation, is probably a key determinant of fetal psychotropic exposure. Consequently, medications with greater affinity for P-glycoprotein should be associated with lower fetal-to-maternal medication ratios, as has been demonstrated in an investigation of antipsychotic placental passage (Newport *et al.* 2007a). Furthermore, clarification of the factors governing placental passage may ultimately contribute to the development of psychotropic agents with minimal rates of placental transfer (Wang *et al.* 2007).

However, fetal plasma concentrations are not the ultimate measure of functional psychotropic exposure and may even underestimate the more critical measure of fetal brain concentration. Certain physiological attributes of the human fetus, including high cardiac output, increased blood-brain barrier permeability, low plasma protein concentrations and plasma protein binding affinity, and low hepatic enzyme activity (Bertossi *et al.* 1999; Morgan 1997; Oesterheld 1998), may produce higher fetal CNS concentrations of psychotropic medications than might be anticipated from circulating levels. Preclinical investigations by our group have demonstrated that transplacental passage results in high levels in fetal CNS tissues and significant binding at neurotransmitter receptor and transporter sites (Capello *et al.* 2011).

Similar considerations apply when endeavoring to minimize the psychotropic exposure of nursing infants. Because the neonate exhibits low hepatic enzyme activity (Warner 1986) and glomerular filtration and tubular secretion rates (Welch and Findlay 1981), psychotropic exposure may be higher than anticipated for breastfed infants. A model to predict rates of breast milk excretion from characteristics of the molecular structure of candidate medications has been proposed (Agatonovic-Kustrin *et al.* 2002). Such models may allow clinicians to estimate a nursing infant's exposure without subjecting the infant to invasive procedures.

CHAPTER 64

Treatment of Attention-Deficit/Hyperactivity Disorder in Adults

Elizabeth Deckler, M.D.

Barbara Coffey, M.D., M.S.

Definitions and Diagnostic Criteria

DSM-5-TR defines ADHD as "a persistent pattern of inattention and/or hyperactivity-impulsivity that interferes with functioning or development" (American Psychiatric Association 2022, p. 68). Furthermore, the pattern of inattention and/or hyperactivity must be inappropriate for the age. DSM-5-TR also specifies the characteristics of distinctive behaviors that suggest inattention and/or hyperactivity-impulsivity; these behaviors are not merely symptoms of underlying oppositional behavior, hostility, inability to understand instructions, or defiance. DSM-5-TR diagnostic criteria for ADHD (see Box 17-1) also stipulate onset of symptoms prior to age 12, evidence that the condition interferes with daily functioning, hyperactive or inattentive symptoms manifesting in two or more distinct settings, and assurance that the symptoms are not secondary to a psychotic disorder or other mental illness.

Box 64-1. Diagnostic Criteria for Attention-Deficit/Hyperactivity Disorder

A. A persistent pattern of inattention and/or hyperactivity-impulsivity that interferes with functioning or development, as characterized by (1) and/or (2):

   1. **Inattention:** Six (or more) of the following symptoms have persisted for at least 6 months to a degree that is inconsistent with developmental level and that negatively impacts directly on social and academic/occupational activities:

      Note: The symptoms are not solely a manifestation of oppositional behavior, defiance, hostility, or failure to understand tasks or instructions. For older adolescents and adults (age 17 and older), at least five symptoms are required.

      a. Often fails to give close attention to details or makes careless mistakes in schoolwork, at work, or during other activities (e.g., overlooks or misses details, work is inaccurate).
      b. Often has difficulty sustaining attention in tasks or play activities (e.g., has difficulty remaining focused during lectures, conversations, or lengthy reading).
      c. Often does not seem to listen when spoken to directly (e.g., mind seems elsewhere, even in the absence of any obvious distraction).
      d. Often does not follow through on instructions and fails to finish schoolwork, chores, or duties in the workplace (e.g., starts tasks but quickly loses focus and is easily sidetracked).
      e. Often has difficulty organizing tasks and activities (e.g., difficulty managing sequential tasks; difficulty keeping materials and belongings in order; messy, disorganized work; has poor time management; fails to meet deadlines).
      f. Often avoids, dislikes, or is reluctant to engage in tasks that require sustained mental effort (e.g., schoolwork or homework; for older adolescents and adults, preparing reports, completing forms, reviewing lengthy papers).
      g. Often loses things necessary for tasks or activities (e.g., school materials, pencils, books, tools, wallets, keys, paperwork, eyeglasses, mobile telephones).

    h. Is often easily distracted by extraneous stimuli (for older adolescents and adults, may include unrelated thoughts).
    i. Is often forgetful in daily activities (e.g., doing chores, running errands; for older adolescents and adults, returning calls, paying bills, keeping appointments).

2. **Hyperactivity and impulsivity:** Six (or more) of the following symptoms have persisted for at least 6 months to a degree that is inconsistent with developmental level and that negatively impacts directly on social and academic/occupational activities:

   Note: The symptoms are not solely a manifestation of oppositional behavior, defiance, hostility, or a failure to understand tasks or instructions. For older adolescents and adults (age 17 and older), at least five symptoms are required.

    a. Often fidgets with or taps hands or feet or squirms in seat.
    b. Often leaves seat in situations when remaining seated is expected (e.g., leaves his or her place in the classroom, in the office or other workplace, or in other situations that require remaining in place).
    c. Often runs about or climbs in situations where it is inappropriate. (**Note:** In adolescents or adults, may be limited to feeling restless.)
    d. Often unable to play or engage in leisure activities quietly.
    e. Is often "on the go," acting as if "driven by a motor" (e.g., is unable to be or uncomfortable being still for extended time, as in restaurants, meetings; may be experienced by others as being restless or difficult to keep up with).
    f. Often talks excessively.
    g. Often blurts out an answer before a question has been completed (e.g., completes people's sentences; cannot wait for turn in conversation).
    h. Often has difficulty waiting his or her turn (e.g., while waiting in line).
    i. Often interrupts or intrudes on others (e.g., butts into conversations, games, or activities; may start using other people's things without asking or receiving permission; for adolescents and adults, may intrude into or take over what others are doing).

B. Several inattentive or hyperactive-impulsive symptoms were present prior to age 12 years.

C. Several inattentive or hyperactive-impulsive symptoms are present in two or more settings (e.g., at home, school, or work; with friends or relatives; in other activities).

D. There is clear evidence that the symptoms interfere with, or reduce the quality of, social, academic, or occupational functioning.

E. The symptoms do not occur exclusively during the course of schizophrenia or another psychotic disorder and are not better explained by another mental disorder (e.g., mood disorder, anxiety disorder, dissociative disorder, personality disorder, substance intoxication or withdrawal).

Specify whether:

F90.2 Combined presentation: If both Criterion A1 (inattention) and Criterion A2 (hyperactivity-impulsivity) are met for the past 6 months.

F90.0 Predominantly inattentive presentation: If Criterion A1 (inattention) is met but Criterion A2 (hyperactivity-impulsivity) is not met for the past 6 months.

F90.1 Predominantly hyperactive/impulsive presentation: If Criterion A2 (hyperactivity-impulsivity) is met and Criterion A1 (inattention) is not met for the past 6 months.

Specify if:

In partial remission: When full criteria were previously met, fewer than the full criteria have been met for the past 6 months, and the symptoms still result in impairment in social, academic, or occupational functioning.

Specify current severity:

Mild: Few, if any, symptoms in excess of those required to make the diagnosis are present, and symptoms result in no more than minor impairments in social or occupational functioning.

Moderate: Symptoms or functional impairment between "mild" and "severe" are present.

Severe: Many symptoms in excess of those required to make the diagnosis, or several symptoms that are particularly severe, are present, or the symptoms result in marked impairment in social or occupational functioning.

Although diagnostic criteria for children, adolescents, and adults are the same, the number of criteria that must be met differs between youth and adults. For both attention symptoms and hyperactivity/impulsivity symptoms, at least five out of the nine criteria must be met to establish a diagnosis of ADHD in adults, and at least six of nine in individuals less than 17 years of age.

ADHD is a common psychiatric disorder; approximately 4% of adults are estimated to suffer from the disorder worldwide. The disorder was first acknowledged in the scientific literature in 1775 in a German textbook written by Melchior Adam Weikard. Despite ADHD's long history and prevalence, it has been strikingly unrecognized in adults. Experts believe that ADHD was underdiagnosed and unrecognized in adults until the 1990s, over 200 years after its establishment in the scientific literature. ADHD, one of the most pervasive psychiatric conditions among children, often fails to remit as these children enter adulthood. Agnew-Blais *et al.* (2016) reported that 21.1% of children diagnosed with ADHD in childhood continued to have symptoms that met criteria for that diagnosis at 18 years of age. Even some subclinical or subthreshold ADHD symptomatology can be problematic and interfere with social, educational, and occupational functioning. Brown and Casey (2016) found that college students with subclinical

ADHD symptoms also experienced problems with externalizing behaviors and executive functioning.

Although many young adults with ADHD may not have symptoms that meet the full diagnostic criteria after a childhood diagnosis, the vast majority retain at least some symptoms and/or functional impairment (Faraone *et al.* 2016). Faraone *et al.* (2006) took a closer look at the threshold of symptoms required for a diagnosis of ADHD. The study investigated whether degrees of functional impairment and psychiatric comorbidity in patients with subthreshold and late-onset ADHD were similar to those in patients with a formal diagnosis of ADHD. Researchers found that patients with late-onset ADHD experienced functional impairment and psychiatric comorbidity at rates similar to those among patients with "full" ADHD. Patients with subthreshold ADHD did not have impairment and comorbidity to the degree that those with full ADHD did, but in comparison with patients without ADHD, they were significantly more afflicted. Compared with patients without ADHD, patients with subthreshold ADHD had higher rates of academic and occupational difficulties. Oppositional defiant disorder was also more prevalent among patients with subthreshold ADHD (Faraone *et al.* 2006). Thapar and Cooper (2016) drew a similar conclusion: patients with subthreshold ADHD experienced poorer academic achievement compared with patients without ADHD. The investigators noted that there was no definite threshold of ADHD symptoms that guaranteed impairments.

Until recently, ADHD was not recognized as a clinical entity among adults. ADHD symptoms in adults have been particularly difficult to identify; they typically differ from those in children, in that the attention deficit is the primary concern, not the motoric hyperactivity. Whereas children with ADHD experience inattention and difficulty with focus and concentration, adults with ADHD may present with an inability to complete tasks at work or school. The hyperactivity that is a hallmark of childhood ADHD typically appears as restlessness in adults. Neither restlessness nor problems at work or school may be interpreted as pathological by clinicians, and may not be immediately recognized as signs and symptoms of adult ADHD. The lack of recognition of the clinical significance of adult ADHD has been problematic, considering that 3.2% of adult women and 5.4% of adult men have symptoms that meet diagnostic criteria (Faraone *et al.* 2006). Interestingly, the ratio of men to women with adult ADHD is about 1:1, in contrast to youth ADHD, in which the ratio of boys to girls is 4:1.

The age at onset of ADHD has recently been questioned by some investigators. Since ADHD is classified as a neurodevelopmental disorder, symptoms must be present before age 18; however, studies have shown that many adult ADHD patients deny or were not aware of symptoms in childhood. Thapar and Cooper (2016) examined the results of multiple studies on adult-onset versus childhood-onset ADHD. They concluded that adult-onset and childhood-onset ADHD were phenotypically similar conditions with different underlying neural mechanisms and causal influences.

Neurobiology: Genomics and Neuroimaging

Genomics

Research has established that genetic vulnerability plays a substantial role in the presentation and development of ADHD, with about 80% of the phenotypic differences accounted for by genetics. Zametkin and colleagues first reported in 1998 that differences in the dopamine transporter gene may be linked to the development of ADHD (Zametkin and Liotta 1998). More recently, another research team investigated the relationship between genes responsible for sphingolipid metabolism and ADHD (Henriquez-Henriquez *et al.* 2020). This study was groundbreaking, considering that prior research had shown that patients with ADHD may have differences in myelination compared with control subjects. The 2020 study concluded that ADHD was correlated with variations in eight of the genes responsible for sphingolipid metabolism. ADHD and ADHD-like symptoms are also often found in individuals with genetic syndromes such as Williams syndrome, 22q11 microdeletion, fragile X syndrome, and tuberous sclerosis and are manifestations of the underlying biological etiology (Henriquez-Henriquez *et al.* 2020).

Neuroimaging

In addition to genetics, numerous neurobiological factors have been established in the pathophysiology of ADHD. Neuroimaging has been an invaluable tool in understanding ADHD. In a groundbreaking review, Zametkin and Liotta (1998) concluded that there were various differences in both structural and functional brain imaging between individuals with ADHD and a control group. Patients with ADHD demonstrated differences in basal ganglia anatomy and glucose metabolism. Structural differences were also seen in the corpus callosum, caudate, and cerebral cortex. Decreased total cerebral volume was found in patients with ADHD compared with control subjects. The investigators reported that dopamine, serotonin, and norepinephrine were uniquely responsible for the behavior changes observed in individuals with ADHD, arguing that the interplay between norepinephrine and dopamine was especially critical. Zametkin and Liotta cited a prior study (Oades 1987) that reported that dopamine abnormalities were responsible for behavioral changes such as inattention, tics, self-mutilation, and hyperactivity. Additionally, the investigators cited a study (Mercugliano 1995) that concluded that dysfunction of the frontal striatum may play a role in the development of ADHD. These findings support the concept that dopamine and norepinephrine play a significant role in the symptomatology of ADHD (Zametkin and Liotta 1998).

Changes in morphological appearance of the cortex and catecholamine signaling have both been associated with the neurobiological mechanisms of ADHD. Cherkasova and colleagues, in 2017, sought to determine the relationship between cortical morphology and catecholamine signaling in patients with ADHD. These investigators found that ADHD patients were likely to have a thinner cortex in regions of the brain associated with the dopamine D_2 and D_3 receptors. Interestingly, the study identified a possible association between cortical thickness and dopamine transmission in patients who were treatment naive and had confirmed ADHD. This finding suggests that neurobiological changes in patients with ADHD may be independent from changes associated with treatment (Cherkasova *et al.* 2017).

Psychiatric Comorbidity

In children, a diagnosis of ADHD is frequently associated with comorbid psychiatric disorders such as tic disorders, learning disorders, intellectual developmental disorder

(intellectual disability), oppositional defiant disorder, conduct disorder, and autism spectrum disorder. As with youth, adults with ADHD have been reported to have a high prevalence of psychiatric comorbid disorders. Longitudinal studies have demonstrated that ADHD is associated with numerous psychiatric comorbidities and social impairments. In a study by Ramos Olazagasti *et al.* (2013), risky behavior in adults with ADHD was associated with increased medical comorbidity; however, only study participants with a dual diagnosis of antisocial personality disorder/conduct disorder and ADHD were found to have increased medical comorbidities. The study authors also found that early use of ADHD medications was protective against and not associated with increased medical comorbidities over time (Ramos Olazagasti *et al.* 2013). Similarly, Thapar and Cooper (2016) reported that although ADHD is not associated with increased medical comorbidity, there is an increased overall risk of mortality. According to their findings, the increased risk in mortality is linked to accidents and a dual diagnosis of antisocial personality disorder, substance use disorder, or oppositional defiant disorder (Thapar and Cooper 2016).

That same study also noted that patients with ADHD experienced more psychosocial problems compared with patients without ADHD (Thapar and Cooper 2016). ADHD was a strong predictor of drug misuse in adolescence and antisocial behaviors, leading to involvement with law enforcement. Interestingly, the meta-analysis found that 26% of incarcerated adults suffered from ADHD. Pharmacological treatment has been found to decrease the rate of criminal activity among ADHD patients, and the alarmingly high prevalence of ADHD among imprisoned adults highlights the necessity for earlier intervention (Thapar and Cooper 2016).

Adler *et al.* (2011) reported that older ADHD patients had impairments in three critical life domains: home, social, and work. Patients were found to be at a significantly higher risk of dropping out of high school compared with their counterparts without ADHD. Occupational problems in ADHD patients included being fired from a job or reprimanded at work, being tardy at work, being unemployed, and having multiple jobs. Compared with those without ADHD, individuals with ADHD were found to have poorer relationships with their parents. They also had higher rates of sexually transmitted infections and were twice as likely to divorce. Patients with ADHD were also less likely to have saved for retirement, but more likely to have been arrested or involved in a motor vehicle accident. Adler et al.'s study posited that treatment should focus not only on treatment of the psychiatric symptoms of ADHD but also on the psychosocial problems associated with the disorder. Adler *et al.* (2011) reported that in addition to pharmacotherapy, cognitive-behavioral therapy (CBT) could be beneficial for both the comorbid anxiety and depression and the psychosocial impairments from which patients may suffer.

Katzman *et al.* (2017) reported that commonly co-occurring disorders in adults with ADHD include anxiety, depression, substance use disorder, personality disorder, and bipolar disorder. The authors argued that the overlap among symptoms of ADHD, the comorbidities, and symptoms of each individual comorbid disorder was so robust that ADHD should be viewed as a spectrum of disorders instead of a single, categorical disease. The rate of comorbid psychiatric disorders among patients with ADHD is astoundingly high, and the Katzman team cited a prior study concluding that 65% of patients younger than 18 years had comorbid bipolar disorder (Tamam *et al.* 2008). Katzman and colleagues also reported that comorbid ADHD was present in 7.8% of patients with depression. The rate of anxiety disorders in individuals with ADHD was nearly 50%, while the rate of personality disorders was over 50%. Although the authors did not report a specific percentage of adult patients with ADHD with comorbid substance use disorders, they noted that patients with ADHD were found to use substances at a younger age compared with their counterparts without ADHD, experienced increased difficulty in achieving abstinence, and had higher rates of polysubstance abuse. Importantly, Katzman *et al.* (2017) reported that early treatment with stimulants may prevent psychiatric comorbidities later in life.

Long-Term Outcomes

ADHD has been associated with several significant negative functional outcomes. Klein *et al.* (2012) evaluated long-term outcomes of patients with ADHD. They found that participants diagnosed with ADHD had, on average, 2.5 fewer years of education and decreased occupational success compared with the control group. They also reported that the group with a diagnosis of ADHD had almost triple the rate of incarceration and death compared with the control group. Patients with ADHD also report higher rates of divorce and marital difficulties compared with control subjects (Klein *et al.* 2012).

Clinical Evaluation

Because there is no specific diagnostic test for ADHD in adults, a detailed, comprehensive history from the patient is essential. It is often helpful to obtain information from the spouse, because ADHD symptoms frequently impact family relationships. If available, childhood history from parents of adults can be helpful, including school records and report cards. A thorough medical workup, including physical examination and laboratory assessment, should be completed. Evaluation for obesity, thyroid disease, and sleep disorders should be performed. For example, hyperthyroidism could be the cause of hyperactivity, and hypothyroidism the cause of inattention. Sleep disorders, such as sleep apnea, which is compounded by obesity, could result in increased daytime sleepiness and inattention. Neurological disorders such as dementia, traumatic brain injury, vascular disease, and stroke should be ruled out. Additionally, hormonal changes in women should be considered in the differential. A comprehensive review of medications is critical for the medical workup of ADHD; anticholinergics, antihistamines, bronchodilators, anticonvulsants, muscle relaxants, and narcotics can be potential causes of ADHD-like symptoms.

In adults who are candidates for medication, particular attention to cardiovascular status should be paid. A detailed cardiovascular history should be taken, and a baseline electrocardiogram is recommended. In individuals with a history of cardiovascular disease, additional consultation with a cardiologist and an echocardiogram may be helpful. Standardized rating instruments, such as the Conners Adult ADHD Rating Scale, Adult ADHD Clinical Diagnostic Scale, Adult ADHD Self-Report Scale, Brown Attention-Deficit Disorder Symptom Assessment Scale, Barkley Adult ADHD Rating Scale, Wender Utah Rating Scale, Clinical Global Impression (CGI) scale, and

Patient Global Impression--Improvement scale, can be useful in the evaluation of symptom severity. Neuropsychological testing may be indicated to differentiate underlying learning disorders and/or executive functions problems, which frequently co-occur, from ADHD.

Specific neuropsychological assessment of executive functions should be included, because problems in this area frequently co-occur with ADHD. Frequently used neuropsychological assessment tools include the Wechsler Adult Intelligence Scale--Revised (WAIS-R) Similarities test, Wisconsin Card Sorting Test, Controlled Oral Word Association Test, WAIS-R Block Design test, Rey-Osterrieth Complex Figure Test, Embedded Figures Test, California Verbal Learning Test, Wechsler Memory Scale, Trail Making Test, WAIS-R Digit Symbol test, Continuous Performance Test, and the 3RT Test Simple task. These tests assess a variety of functional domains often implicated in ADHD-related problems, such as verbal intelligence, fluency, executive functions, visual-figural problem-solving, abstract problem-solving, working memory, simple attention, sustained attention, focused attention, verbal memory, and figural memory.

Overview of Treatment

The goal of treatment of ADHD in adults is to reduce symptoms, alleviate distress and impairment, and improve quality of life. Because adult ADHD symptoms are likely to impact family members, it may be helpful to include the spouse in treatment planning. Successful treatment response is measured by reduction in clinical symptoms and functional impairment. Although there are no specifically recommended quantitative measures of treatment response in adults, most practitioners aim for a 30% reduction in ADHD symptoms. CGI-Improvement scores for ADHD symptoms may be helpful to monitor response.

Pharmacological Treatments

Investigation of pharmacological treatment of adult ADHD has only rather recently been established. Studies examining safety and effectiveness of adult ADHD treatments have lagged behind those of children and adolescents. As with youth, stimulants are generally recommended as first-line pharmacotherapy for adults with ADHD. Although controlled studies in children and adolescents typically report a response rate of 70%, response rates in controlled trials of adults are more variable, ranging from 25% to 78% (Wilens *et al.* 2011). Wilens and colleagues reported a short-term controlled weighted mean response rate of 60% and a longer-term weighted mean of 74%. As in youth, efficacy rates for amphetamines and methylphenidate are similar in adults. Variable adult response rates may be a function of differences in diagnostic criteria, dose range, impact of psychiatric comorbidity, and lack of consistent response measures.

Unlike in children and adolescents, there are very few studies evaluating the efficacy of individual pharmacological treatments of ADHD in adults. To date, there are no head-to-head studies available.

Simon *et al.* (2015) reported that stimulants are currently the first-line medication choice for treatment of ADHD symptoms, given their mechanistic ability to block norepinephrine and dopamine transporters, resulting in increased dopamine in the

extracellular space. The authors recommend a sustained-release version of stimulant medications, which is typical of current practice (Simon *et al.* 2015). Important aspects of each medication are outlined in Table 64-1. Efficacy parameters of FDA-approved pharmacological treatments are summarized in Table 64-2.

TABLE 64-1. Pharmacological treatment of ADHD in adults

Treatment	**Mechanism of action**	**Recommended dosage range**	**FDA approved for treatment of ADHD in adults**	**Strength of evidence**
Dextroamphetamine-amphetamine	Blocks dopamine, norepinephrine, and serotonin reuptake, and increases release from the presynaptic terminal	5-40 mg/day	Yes	Strong
Lisdexamfetamine	Blocks dopamine, norepinephrine, and serotonin reuptake, and increases release from the presynaptic terminal	10-70 mg/day	Yes	Strong
Methylphenidate	Inhibits reuptake of dopamine and norepinephrine and	5-60 mg/day	Yes	Strong

Treatment	Mechanism of action	Recommended dosage range	FDA approved for treatment of ADHD in adults	Strength of evidence
	promotes dopamine release			
Atomoxetine	Selectively inhibits norepinephrine reuptake	40-80 mg/day	Yes	Strong
Guanfacine (extended release)	Inhibits norepinephrine release and activates a_{2a}-adrenergic receptors	1-4 mg/day	No	Moderate
Clonidine	Activates a_{2a}-adrenergic receptors	0.1-0.4 mg twice a day	No	Moderate
Bupropion	Unknown	200 mg, up to 450 mg	No	Moderate

TABLE 64-2. Efficacy of FDA-approved pharmacological treatments

Treatment	Efficacy
Amphetamine	Weighted mean approximately 61% response vs. 20% placebo

Treatment	Efficacy
	Decrease in ADHD symptom scores on Clinical Global Impression scale of 33%
Lisdexamfetamine	Statistically significant improvement in ADHD symptoms vs. placebo
	Remission of symptoms achieved in 64%-72.1% of study participants
Methylphenidate	Weighted mean approximately 60% response vs. 26% placebo
	Number needed to treat (NNT) = 1.1
Atomoxetine	Statistically significant improvement in ADHD symptoms vs. placebo
	NNT = 4

Stimulants

There are two classes of CNS stimulants for treatment of ADHD in youth and adults, which include amphetamines and methylphenidate. Because of their abuse potential, both medication classes are designated Schedule II controlled substances as classified by the FDA. It is important to note that stimulants should not be used to treat hyperactivity or impulsivity in individuals whose symptoms are secondary to a comorbid psychiatric illness or environmental factors.

Dextroamphetamine-Amphetamine

The amphetamines are CNS stimulants that reduce hyperactivity and impulsivity and other ADHD symptoms. Amphetamine blocks the reuptake of dopamine and norepinephrine in the presynaptic cleft and promotes intracellular release. The peak plasma concentration of amphetamine is reached approximately 3 hours after administration. The half-life of the medication follows pharmacokinetics that are proportional to the dose.

Amphetamine was first discovered in 1937 by Charles Bradley. At that time, he tested the efficacy of Benzedrine, an original amphetamine enantiomer, in 30 school-age children. He found that there was a significant increase in school performance among study participants that was entirely attributable to the use of the drug.

Amphetamine is FDA approved for the treatment of narcolepsy and ADHD. Mixed amphetamine salts, currently the most commonly prescribed amphetamine for youth, are a mixed enantiomer version of amphetamine. In general, the amphetamines are relatively well tolerated in youth and most adults. The more common adverse effects that have been reported in association with use of amphetamine are cardiovascular events, hypertension, worsening and induction of psychosis, precipitation of a mixed/manic episode in patients with preexisting bipolar disorder, tics, visual disturbances, seizures, and aggression. In children, stimulants may be associated with suppression of long-term growth (Heal *et al.* 2013).

Lisdexamfetamine

Lisdexamfetamine is FDA approved for treatment of ADHD in children older than 6 years, adolescents, and adults. It is an amphetamine prodrug with a metabolic route distinct from that of the other amphetamines, in that it is broken down by red blood cells to create D-amphetamine and L-lysine. Lisdexamfetamine is a long-acting formulation, and thus there is less abuse potential (Heal *et al.* 2013).

Methylphenidate

Methylphenidate is a CNS stimulant with a mechanism of action distinct from that of amphetamine. It was first discovered in 1944 by the Ciba-Geigy Pharmaceutical Company. Now known as Novartis, the formulation was patented by Ciba-Geigy in 1954 under the trade name Ritalin. Methylphenidate is FDA approved for the treatment of ADHD in patients older than 6 years.

Methylphenidate is believed to both inhibit the reuptake of dopamine and norepinephrine and promote their release. Although the full mechanism of action is still unknown, methylphenidate has been proven to decrease hyperactivity and impulsivity. It has a half-life ranging from 2 to 7 hours and reaches its peak concentration 1-2 hours after administration.

The most commonly reported adverse effects of methylphenidate are appetite suppression and initial insomnia. Nervousness and tachycardia are also not uncommon. The insomnia caused by methylphenidate use can typically be alleviated by dosing in the morning instead of in the afternoon or evening. Cardiovascular effects are more likely in adults than in youth, and a medical workup is recommended prior to initiation (Heal *et al.* 2013).

Long-Acting Formulations

Long-acting formulations of stimulant medications are increasingly used in clinical practice for practical reasons. Both with youth and adults, once-a-day administration makes it more feasible to treat symptoms during the course of the schoolday or workday. Long-acting formulations are also often prescribed for individuals with ADHD and comorbid substance abuse because of their decreased abuse potential compared with short-acting formulations.

Pharmacological treatment of ADHD has been associated with improved long-term outcomes. Roy *et al.* (2018) took a closer look at predictors in childhood that had an impact on long-term functional outcomes of patients enrolled in the Multimodal Treatment of Attention Deficit Hyperactivity Disorder study (MTA). The authors concluded that early diagnosis and intervention in children with ADHD led to better functional outcomes as adults. Recognition and treatment of ADHD symptomatology were uniquely beneficial (Roy *et al.* 2018). Shaw *et al.* (2012), in a systematic review in 2012, came to similar conclusions. The review examined 30 years of studies on the impact of ADHD treatments on long-term outcomes. The authors reported that treatment reduces the negative impact ADHD can have on overall functioning. Untreated patients were found to have more severe impairments in functioning. Interestingly, patients treated for ADHD were not found to be at a higher risk of substance abuse compared with untreated patients. Of note, untreated

ADHD patients were more likely to experiment with cocaine compared with treated patients. Additionally, treatment for ADHD was found to decrease antisocial behaviors, drug use, and addictive behaviors. Treatment improved occupational and academic outcomes of patients as well. Research has also shown that pharmacological treatment of ADHD is associated with a decreased incidence of trauma-associated hospital visits and criminal activity (Shaw *et al.* 2012).

Unfortunately, long-term treatment with stimulants has been correlated with lower adult height. Greenhill *et al.* (2020) reviewed long-term outcomes of the original participants in the MTA and concluded that compared with the minimally medicated group, patients with 16 or more years of consistent stimulant use had slightly lower height on average in adulthood (Greenhill *et al.* 2020).

Nonstimulant Medications

Nonstimulant medications, including atomoxetine, a_2 agonists, bupropion, and tricyclic antidepressants, offer patients additional options for ADHD symptom relief. They are recommended for stimulant nonresponders and for adults with ADHD and significant comorbidity. Stimulant-naive patients may respond more robustly to atomoxetine when it is used before stimulants. Although the majority of children and adolescents benefit from treatment with a stimulant, there are fewer data regarding therapeutic adult response. Adults with ADHD tend to have more psychiatric comorbidity, including substance use disorders, which are common. It is estimated that 15%-20% of adults with a diagnosed substance use disorder carry a dual diagnosis of ADHD. Nonstimulant medications offer additional treatment options for individuals considered at high risk for medication misuse.

Although patients with ADHD are at a higher risk of substance abuse over their lifetimes, treatment of ADHD has been associated with a decreased risk of substance abuse. Quinn *et al.* (2017) reviewed 2,993,887 health care claims of children and adolescents over a 9-year period. The study evaluated the relationship between substance abuse and ADHD treatment and found that stimulant treatment of ADHD was not associated with an increased risk of substance abuse. Interestingly, treatment of ADHD was found to be protective against substance abuse. The study noted its similarity to a Swedish study (Chang *et al.* 2014) that also found a decreased incidence of substance abuse among patients treated with stimulants for ADHD. The Swedish study similarly concluded that stimulants were protective against future substance abuse (Quinn *et al.* 2017).

Guanfacine and clonidine have not been FDA approved for the treatment of ADHD in adults; however, they are included in this chapter because of the extant research on their effectiveness as off-label treatments.

Atomoxetine

Atomoxetine was the first medication to be approved by the FDA for treatment of ADHD in adults. It is unique among the nonstimulant medications in that it is a selective norepinephrine reuptake inhibitor. Originally intended for use as an antidepressant, atomoxetine was reported to decrease ADHD symptoms in trial participants. This medication is FDA approved for treatment of ADHD in children, adolescents, and adults. It is given in dosages ranging from 40 mg/day to 80 mg/day. It may be useful in adults with ADHD who have co-occurring substance use, anxiety, or tic symptoms.

Adverse effects may include nausea, weight changes, insomnia, constipation, dizziness, and sexual dysfunction. Atomoxetine has been assigned a black box warning for increased risk of suicidal ideation in children, adolescents, and young adults, but there have been no reports of suicidality in adults with ADHD. Individuals at risk for bipolar disorder should be closely monitored, because atomoxetine may increase risk of bipolar symptoms (Huang *et al.* 2020).

Guanfacine

Guanfacine is an a-adrenergic agonist effective in treatment of ADHD symptoms. In addition to its a-adrenergic effects, guanfacine inhibits the release of norepinephrine. It normalizes the balance between dopamine and norepinephrine in the amygdala through alteration of hyperpolarization-activated cyclic nucleotide-gated potassium channels. Guanfacine is available in short-acting and long-acting formulations. The long-acting formulation of guanfacine is the only one of the two that is FDA approved for treatment of ADHD; however, it is FDA approved for treatment of ADHD only in youth. It can be used both as a monotherapy and as an adjunct to other ADHD medications. It is given once daily, and the recommended dosage ranges from 1 mg/day to 4 mg/day. As the a-agonists have cardiovascular effects, blood pressure and heart rate should be monitored in patients taking guanfacine for ADHD (Iwanami *et al.* 2020a, 2020b).

Clonidine

Similar to guanfacine, clonidine hydrochloride is an a-adrenergic agonist that is effective in treating ADHD symptoms. It is available in a short-acting formulation and in an extended-release formulation. Like guanfacine, it has not been FDA approved for the treatment of adults with ADHD or in children younger than 6 years, but it can be used off-label. The recommended dosage ranges from 0.1 mg/day to 0.4 mg/day, typically given in twice-a-day dosing (Mattes 2016).

Bupropion

Bupropion is an antidepressant with mixed catecholamine effects that is FDA approved for treatment of major depressive disorder and seasonal affective disorder. It is used off-label for treatment of ADHD. Bupropion is offered in a sustained-release and an extended-release formulation. For the treatment of ADHD, the sustained-release formulation is given at dosages up to 200 mg/day; clinical effects last about 12 hours. The extended-release formulation is given at dosages up to 450/day, and the clinical effects last about 24 hours (Huang *et al.* 2020).

Tricyclic Antidepressants

Despite substantial use in youth, there are only two studies of tricyclic antidepressants in adult ADHD. A controlled study of desipramine at dosages up to 200 mg/day resulted in reduction of symptoms in as little as 2 weeks' time (Wilens *et al.* 2011).

Treatment of Adult ADHD With Comorbid Psychiatric Disorders

ADHD often co-occurs with other psychiatric disorders. The recommended treatment approach in adults with ADHD and psychiatric comorbidity is to treat the disorder causing the most distress and/or impairment first. In cases of mild depression, CBT can be helpful for both the depression and the ADHD. Stimulants have successfully been given in combination with antidepressants in patients with more impairing depressive disorders. Bupropion could be considered a first-line treatment of patients with ADHD and comorbid major depressive disorder as monotherapy; a selective serotonin reuptake

inhibitor antidepressant and a long-acting stimulant could also be beneficial. Tricyclic antidepressants, such as desipramine and nortriptyline, and selective serotonin-norepinephrine reuptake inhibitors, such as venlafaxine, have also been used as monotherapy. Other options include antidepressants used in combination with a short-acting stimulant, atomoxetine, or lisdexamfetamine. In patients with bipolar disorder in which a stimulant could precipitate a manic episode, bupropion or other nonstimulant medications should be considered after the mania has resolved. Interestingly, stimulants have not been found to increase anxiety symptoms in patients with ADHD and comorbid anxiety disorders. For patients with substance use disorders, most experts recommend treatment of the substance use disorder first, followed by treatment of the ADHD once the substance use disorder has remitted. Treatment of ADHD symptoms has been found not only to reduce the severity of comorbid substance abuse, depression, anxiety, and bipolar disorder but also to be protective against future psychiatric illness.

Psychosocial Treatment Options

Nonpharmacological treatment options for ADHD include CBT, dialectical behavior therapy, and mindfulness. Studies on the efficacy of nonpharmacological treatments for ADHD have reported benefit in children and adolescents. CBT is considered a mainstay in the treatment of ADHD; however, despite the availability and increasing popularity of CBT, dialectical behavior therapy, and mindfulness, research has shown a clear benefit of pharmacological treatments over nonpharmacological treatments.

Coaching and assistance with executive functioning have been found to be uniquely helpful in ADHD patients. Coaching is a relatively new treatment modality in ADHD; the intervention involves a patient working with a coach one-to-one or in a group setting. Coaching has been found to help patients meet individual treatment goals; the coach teaches patients how to maintain focus, build motivation, and overcome impairments. A major aspect of coaching is helping patients gain insight into their condition and recognize their impairments (CHADD 2021).

Although pharmacological treatments have been found to be superior, psychosocial treatments can be useful adjuncts for ADHD. A 2019 study of adult ADHD compared CBT treatment alone and CBT treatment in combination with a psychotropic medication. The study concluded that CBT is efficacious in treating adult ADHD; however, the combination of CBT and pharmacotherapy in adults with ADHD also improved executive functioning (Pan *et al.* 2019).

Combination Treatments

Research has shown that a combination of pharmacotherapy and psychosocial treatment is more beneficial than either treatment alone. Psychosocial treatments should be unique to each patient, addressing specific symptoms that are problematic. Ramos Olazagasti *et al.* (2013) recommended that adults with ADHD undergo psychosocial treatment for academic difficulties, tardiness, and maintenance of relationships, as well as other problems. CBT is a mainstay in the treatment of adult ADHD and focuses on giving patients tools to control impulsive behavior (Ramos Olazagasti *et al.* 2013).

In addition to the combination of pharmacotherapy and psychotherapy treatment, multiple ADHD medications have been used, off-label, in combination in patients who did not show an adequate response to monotherapy. Treuer *et al.* (2013) reported that the combination of atomoxetine and a stimulant was beneficial in some patients whose symptoms were not adequately controlled on one medication alone. The study did not find any additional safety concerns when using the medications in combination.

Recommendations and Clinical Applications

ADHD symptoms often persist into adulthood and carry concomitant risks of significant psychiatric comorbidity, functional impairment, and reduced quality of life. Comprehensive medical and psychiatric evaluation is indicated in adults to confirm an ADHD diagnosis and rule out other medical or psychiatric disorders, which frequently co-occur. Neuropsychological assessment of potential associated executive function problems is often necessary. Once a diagnosis has been confirmed, psychoeducation regarding ADHD outcomes and treatment is necessary. Adults with ADHD can be treated with the full range of pharmacological and psychosocial treatments available to youth. Because psychiatric comorbidity is the rule rather than the exception in adult ADHD, combination treatments are often necessary.

CHAPTER 65

Treatment of Individuals With Intellectual Developmental Disorder

Katharine Stratigos, M.D.
Julia Katz, M.D.
David Hong, M.D.

In this chapter we focus on the pharmacological management of individuals with intellectual disability (ID) or intellectual developmental disorder (IDD). We will primarily use the term *IDD* here, although in practice the terms are used interchangeably. ID and IDD are a positive transition from the older classification, *mental retardation*, used in prior DSM editions. Care of individuals with IDD necessarily involves a comprehensive interventional approach that encompasses multiple systems of care and typically spans many decades of development, as reflected in the name of the condition. Therefore, use of psychotropic medications in this population is only one facet of the treatment plan, albeit an important one. Space limitations preclude an exhaustive overview of the myriad issues involved in providing care for this underserved population, so here we focus on treatment guidelines, with an emphasis on controlled studies in the IDD literature; additional resources are available that are wholly dedicated to IDD diagnosis and management, such as the Diagnostic Manual--

Intellectual Disability 2 (DM-ID-2; Fletcher *et al.* 2017). This chapter is intended to assist the general psychiatrist in making informed treatment decisions about pharmacotherapy, as well as in managing unique issues that arise in psychiatric treatment of individuals with IDD.

Background

IDD is a common condition, with estimates of total prevalence ranging from 0.7% to 1.35% (Boyle *et al.* 2011; Zablotsky *et al.* 2017). Presentation of IDD varies widely with regard to symptom severity, which is highlighted by increased emphasis on adaptive functional impairment in DSM-5 (American Psychiatric Association 2013). Indeed, diagnosis of IDD has gradually moved away from reliance on cognitive measurement of intellectual ability and increasingly toward operationalization of the impact of intellectual deficits on adaptive functioning. Unsurprisingly, mild IDD is more frequently identified in the broader population, whereas the prevalence of severe IDD (defined by approximate IQ < 35-40) is estimated at 2.5-6/1,000 children (American Psychiatric Association 2013; Committee to Evaluate the Supplemental Security Income Disability Program for Children with Mental Disorders *et al.* 2015).

DSM-5 specifies that for a diagnosis of an IDD, the individual must demonstrate deficits in intellectual functions, which may include deficits in reasoning, problem-solving, planning, abstract thinking, judgment, academic learning, and learning from experience. The presence of these impairments is confirmed through a clinical assessment involving IQ testing (e.g., Wechsler Intelligence Scale for Children, Wechsler Adult Intelligence Scale, Stanford-Binet Intelligence Scales) with results greater than two standard deviations below the mean (i.e., 70). The individual must also demonstrate deficits in adaptive functioning, and in fact, DSM-5 emphasizes this component more than previous editions. Such limitations prevent the individual from meeting developmental and sociocultural standards for independence and responsibility and involve limitations in one or more adaptive living skills, such as communication, independent living, and personal hygiene. Adaptive functioning reflects everyday functioning in the real world and includes practical activities of daily living, as well as social functioning and communication. Adaptive functioning is typically assessed via the Vineland Adaptive Behavior Scales, on which individuals with IDD score in the low range of functioning. Finally, the onset of disability must be during the developmental period (e.g., childhood), and thus an adult with new-onset cognitive limitations (e.g., traumatic brain injury, dementia) would not meet criteria for IDD.

There are multiple levels of severity, from mild to profound symptom burden (Table 65-1), and understanding the patient's level of IDD informs providers' ability to formulate an appropriate treatment plan. Approximately 78% of individuals with IDD have *mild* IDD, with a full-scale IQ of approximately 55-70 (Patrick *et al.* 2021), representing academic skills up to about the sixth-grade level. An individual with mild IDD will have some skills for independent functioning but will need support under stress. Individuals with *moderate* IDD represent approximately 12% of the IDD population (full-scale IQ: 35-40 to 50-55 [Patrick *et al.* 2021]). Their adjusted developmental age is approximately 6-9 years, and their presentation may be deceptive because of their varying cognitive profiles. For instance, language may range from actual conversations to the limited communication of basic needs (ranging from phrase speech to sentences). Individuals with strong language skills may confuse others into thinking that they understand and can manage more than they can. Individuals with *severe* to *profound* IDD represent about 1% of individuals with IDD and are typically identified very early in development through manifestation of motor and early language deficits. Individuals will have limited speech (e.g., single words or nonverbal) but may have stronger receptive language skills. Adults with severe IDD need lifelong assistance and highly supervised settings (e.g., group residences). They frequently have autistic features but may still form strong attachments to caregivers (Harris 2006). It is worth underscoring that IDD and autism spectrum disorder (ASD) are frequently comorbid, with approximately one-third (35%) of children with ASD also carrying a diagnosis of IDD (Maenner *et al.* 2021). Pharmacological management of ASD is discussed in Chapter 66, "Treatment of Autism Spectrum Disorder."

TABLE 65-1. Severity levels in intellectual developmental disorder

Severity level	**IQ**	**Adjusted developmental level**	**Language**	**Skills**
Mild	50-55 to 70	Ages 9-12 years	Simple sentences and conversations	Skills for some self-support; needs assistance under stress
Moderate	35-40 to 50-55	Ages 6-9 years	Sentences to phrases, varies	Needs sheltered conditions; can reach ~ 2nd grade academic level
Severe	20-25 to 35-40	Ages 3-6 years	Single words, limited spoken language	Minimal self-care, poor motor and language development; needs full supervision
Profound	20-25	Age < 3 years	Spoken language: very limited to none	Needs constant assistance and supervision

Source. Harris 2006.

Neurodevelopmental Framework

Given the typically early age at diagnosis of developmental disabilities and the age criterion in DSM-5, psychiatrists specializing in child and adolescent treatment are often the first to provide care. Notably, time dedicated to mastery of IDD is limited in child fellowship training, averaging as few as 3 hours of didactic instruction and one to five outpatient cases yearly (Marrus *et al.* 2014). This training gap is compounded by additional challenges that may manifest in IDD, depending on the severity of symptoms that result in asynchronous progression of chronological and developmental age. Challenges in assessing individuals with IDD include difficulties in obtaining subjective or objective symptom reporting, differentiating between manifestations of IDD and other comorbid psychiatric conditions, implementing treatment strategies effectively relative to neurotypical development, and overcoming logistical obstacles associated with complex health care delivery systems, particularly for individuals with severe IDD. A notable drop-off in services available for adults with IDD occurs as they age out of more comprehensive school and disability service systems, further complicating appropriate diagnosis and pharmacological management in this vulnerable population. Attention to systems of care around individuals with IDD is critical to their care and has important implications for their psychopharmacological treatment. Above all, medications should not be prescribed as the only intervention without other services and treatment provisions in place.

Assessment and Psychopharmacological Treatment Planning

Accurate assessment of psychiatric diagnoses for the purpose of psychopharmacological management is of particular importance in IDD. This assessment requires some adaptation of DSM criteria, especially for individuals with limited language. Assessment during the maintenance phases of pharmacological treatment requires the clinician to observe patients closely for any side effects from psychotropic medication--including extrapyramidal side effects (EPS), tardive dyskinesia, and sedation--that may not always manifest during subjective reporting. Collateral history from caregivers, school, and day programs is likewise of key importance, and descriptions of behaviors in specific contexts or environments, with rigorous behavioral analysis, are often needed to accurately identify the most important symptoms for treatment. It is beyond the scope of this chapter to detail the nuances of differential diagnosis in individuals with IDD, a topic that is comprehensively covered elsewhere (Fletcher *et al.* 2017).

In short, clinicians should maintain alertness for "diagnostic overshadowing"--defined as the misattribution of varying types of symptoms (whether medical, psychiatric, or part of the developmental disability) to an incorrect underlying cause--when assessing individuals with IDD. Examples include mistaking a component of IDD for a psychiatric symptom (e.g., repetitive behaviors in autism are mistaken for OCD) or, conversely, mistaking a component of psychiatric symptoms for a feature of IDD (e.g., a quiet patient is actually depressed, not simply nonverbal) (Jopp and Keys 2001). This error may be responsible for inaccurate diagnoses of bipolar disorder and schizophrenia in the IDD population (Charlot *et al.* 2007). Diagnostic overshadowing often occurs in the context of aggressive behaviors, a common presenting psychiatric problem in individuals with IDD that may be a manifestation of other underlying etiologies, such as medical problems (e.g., pain, infection, gastrointestinal disturbance), limitations in communication, psychosocial changes, trauma, anxiety, or depression. This is particularly relevant, given evidence that nonpsychiatric etiologies that may lead to disruptive behaviors in IDD are often underdiagnosed and undertreated (Axmon *et al.* 2016). To address similar clinical challenges in ASD, McGuire *et al.* (2016) developed clinical pathways for assessing irritability and problem behaviors in ASD, and this approach is also highly applicable to pharmacological assessment in individuals with other developmental disorders and intellectual disabilities. The focus of these clinical pathways is to assess for any contributors to aggression or other problem behaviors, such as medical comorbidities, communication difficulties, psychosocial stressors, negative reinforcement cycles, or co-occurring psychiatric disorders. This pathway approach provides a foundational model for approaching pharmacological management in IDD as well.

Psychopharmacological Treatment in Individuals With IDD

Unfortunately, literature on pharmacological management of IDD is limited. Most medication trials specifically exclude individuals with IDD, and so the evidence base is lacking in both child and adult psychopharmacology studies. Of the few clinical trials specific to IDD reviewed in this chapter, a number are underpowered, rely on nonspecific symptom outcomes (e.g., aggressive behaviors) rather than DSM-5 conditions, and have not been replicated. In the face of limited empirical research in this area, expert clinical consensus guidelines have recently been developed to provide a treatment framework in IDD (National Center for START Services 2023).

In clinical practice, medication strategies often draw on findings from randomized controlled trials (RCTs) in non-IDD populations, based largely on the premise that unless medication effects are influenced by co-occurring medical and neurological disorders, there is limited evidence that IDD itself changes the mechanism of action of psychotropic medications. Thus, while treatment of these conditions often aligns with treatment strategies used in individuals without IDD, particular caution should be taken when prescribing medications that cause or worsen cognitive impairment and sedation (e.g., chlorpromazine, topiramate, diphenhydramine) to individuals whose baseline cognitive functioning is limited. Additionally, individuals with IDD may be both more sensitive to medication side effects and less able to communicate about them.

Challenges in identifying specific pharmacological targets in IDD are due partly to substantial heterogeneity in etiological pathways converging on the IDD phenotype, which encompasses a range of genetic syndromes, prenatal exposures (e.g., alcohol), perinatal factors (e.g., prematurity, hypoxia), and environmental insults. Neurobiological systems affecting cognition are similarly diverse and wide-ranging, encompassing most classic neurotransmitter pathways (Zarrindast 2006). Relatedly, genetic and neurobiological findings implicate neuronal migration, synapse formation and plasticity, and cell signaling pathways, among others (Srivastava and Schwartz 2014; Vissers *et al.* 2016), underscoring the challenges in mapping these mechanistic pathways to tailored psychopharmacological interventions. This heterogeneity probably underlies the absence of disease-modifying treatments for core symptoms of IDD. However, the majority of adults (50%-70%) with IDD take some form of psychotropic medication (Axmon *et al.* 2017; Lunsky and Modi 2018; Tsiouris *et al.* 2013) for comorbid conditions.

Comorbidity in Individuals With IDD

Comorbidity is highly prevalent in the IDD population. Estimates indicate that 30%-50% of children and adolescents with IDD have a concurrent psychiatric diagnosis, compared with 8%-18% of youths without IDD (Einfeld *et al.* 2011). Estimates of psychiatric comorbidity in adults with IDD are similarly wide ranging, with studies reporting that 13%-75% of these individuals have co-occurring psychiatric symptoms (Buckles *et al.* 2013).

Commonly presenting symptoms for pharmacological treatment in this population include irritability; challenging or "problem" behaviors; aggression toward self, others, or objects; hyperactivity; agitation; stereotypies; and perceived oppositional behavior. Notably, anxiety, depression, and PTSD are infrequently discussed in IDD literature and may represent large domains of missed diagnoses in clinical practice. In a recent meta-analysis ($N = 6{,}151$), the most common symptoms for which children and adolescents with IDD presented to psychiatry were those indicating ADHD (30%) and anxiety disorders (7%-34%) (Buckley *et al.* 2020).

Similarly, rates of trauma and abuse were found to be substantially higher in individuals with developmental disabilities than in the general population (Constantino *et al.* 2020), yet they are underdiagnosed and undertreated. Relatedly, relatively benign treatments (e.g., selective serotonin reuptake inhibitors [SSRIs], behavioral therapy) may be overlooked in favor of medications with less favorable side-effect profiles, such as antipsychotics and mood stabilizers.

Psychopharmacological Approaches and Interventions

For reasons outlined above, a clearly determined DSM-5 diagnosis as a treatment target provides reliable guidance for ongoing complex pharmacological management. Medication management for a symptom, such as unspecified aggression, rather than a psychiatric condition, is best limited to situations in which individuals pose a risk of serious injury to self or others or are at risk of losing access to an important service (e.g., needing to move out of their home or change schools), or in which other treatments have failed to improve symptoms despite adequate psychosocial support. Care should be taken to avoid prescribing psychotropic medications for the convenience of the caregiver or as a substitute for a positive behavioral support plan and appropriate wraparound services. In patients with medical comorbidities, opportunities for simplification and consolidation of medication regimens should also be considered (e.g., choosing an anticonvulsant drug with desired psychopharmacotherapeutic effects with comorbid epilepsy). As-needed medication for behavioral symptoms has potential for overuse, necessitating clear and specific indications for use, frequent monitoring, and clear parameters for duration of treatment. Also, a significant concern with prior studies is failure to examine pharmacological effects in conjunction with evidence-based behavioral therapies, which are typically mentioned only insofar as they were included in the research design. There continues to be a lack of robust direct comparison of pharmacological and nonpharmacological treatments, separately or in combination, to guide clinical parameters for multidimensional treatment plans.

Psychopharmacological Management of Irritability and Aggressive Behaviors

Earlier psychopharmacology studies largely reported nonspecific symptom outcomes, including aggression, irritability, self-injurious behaviors (SIBs), and agitation. This tendency reflects clinical practice, where nonspecific irritability and aggressive behaviors are often the leading reasons for referral for psychiatric care. As

discussed previously, these symptoms are often a final common behavioral pathway with multiple possible etiologies, necessitating a thorough behavioral evaluation. When medication is indicated, first-generation and atypical antipsychotics are often used, despite minimal evidence for the benefits of chronic administration (Deb and Unwin 2007; Deb *et al.* 2015; Tyrer *et al.* 2008). Nevertheless, it is estimated that 20%-70% of individuals with IDD who exhibit aggressive or "problem" behaviors receive long-term pharmacological treatment (Axmon *et al.* 2017; Deb and Unwin 2007; de Kuijper *et al.* 2010; Gomes *et al.* 2019; O'Dwyer *et al.* 2016). When appropriate, however, medications judiciously used across shorter durations may be of benefit for symptom reduction.

Antipsychotics

The most robust data for youths with IDD have shown risperidone to improve symptoms of irritability and aggression and problem behaviors associated with disruptive behavior disorders (DBDs) (Table 65-2). In two open-label extension studies (Findling *et al.* 2004; Turgay *et al.* 2002), risperidone's effects were noted within the first 2 weeks of treatment and were sustained. There have also been multiple studies of adults with IDD taking risperidone to address unspecified behavioral symptoms, which showed some positive effects over placebo as measured by improvements in the Aberrant Behavior Checklist (ABC) and Clinical Global Impression (CGI) Scale (Gagiano *et al.* 2005; Vanden Borre *et al.* 1993). In a 48-week open-label follow-up, there was ongoing response and some additional improvement (Gagiano *et al.* 2005). However, increased appetite and weight gain with risperidone are common (Hellings *et al.* 2006) and can be a substantial clinical concern. Olanzapine was also found in open-label studies to decrease aggression and agitation (Handen and Hardan 2006; Janowsky *et al.* 2003a) and was also associated with significant weight gain. Aripiprazole decreased CGI scores in a retrospective chart review, although the sample also included individuals with comorbid ASD (Hellings *et al.* 2011). In contrast, one RCT has called into question the role of medications in treating behavior dysregulation in adult patients with IDD. In a comparison of haloperidol, risperidone, and placebo in the treatment of aggressive behaviors, symptoms decreased substantially by 4 weeks across all treatment arms, but the placebo group showed the greatest improvement (Tyrer *et al.* 2008), a finding possibly underscoring the role of caregiver perceptions of symptomatic behavior and how such perceptions may cloud a true understanding of psychopharmacological response in this population. Overall, existing research is extremely limited, especially in regard to long-term use of antipsychotic medication in the multimodal treatment of individuals with IDD (Deb and Unwin 2007; Duggan and Brylewski 1999; Singh *et al.* 2005).

TABLE 65-2. Summary of risperidone randomized controlled trials (RCTs): psychopharmacological studies of agitation and "problem behavior" in children and adults with intellectual developmental disorder

RCTs	Risperidone dosing range	Side effects[a]	Outcomes
Children			

Note. All RCTs had at least 10 participants/subjects. ABC = Aberrant Behavior Checklist; CGI = Clinical Global Impression Scale; EPS = extrapyramidal side effects; NCBRF = Nisonger Child Behavior Rating Form.

[a] Commonly reported side effects in studies. List is not comprehensive.

RCTs	Risperidone dosing range	Side effects[a]	Outcomes
Aman *et al.* 2002	0.4-4.0 mg/day or 0.01-0.06 mg/kg/day or 0.01-0.09 mg/kg/day (Van Bellinghen and De Troch 2001)	Weight gain, sedation, elevated serum prolactin, mild or no significant EPS	Decreased disruptive behavior (e.g., aggression) and improvement on ABC or CGI (Aman *et al.* 2002; Buitelaar *et al.* 2001; Hellings *et al.* 2006; Van Bellinghen and De Troch 2001; Vanden Borre *et al.* 1993; Zarcone *et al.* 2001)
Buitelaar *et al.* 2001	4-12 mg/day (Vanden Borre *et al.* 1993)		Improvement on NCBRF (Aman *et al.* 2002; Snyder *et al.* 2002)
Hellings *et al.* 2006			
Snyder *et al.* 2002			
Van Bellinghen and De Troch 2001			
Vanden Borre *et al.* 1993			

Note. All RCTs had at least 10 participants/subjects. ABC = Aberrant Behavior Checklist; CGI = Clinical Global Impression Scale; EPS = extrapyramidal side effects; NCBRF = Nisonger Child Behavior Rating Form.

[a] Commonly reported side effects in studies. List is not comprehensive.

RCTs	Risperidone dosing range	Side effects[a]	Outcomes
Zarcone *et al.* 2001			
Adults			
Gagiano *et al.* 2005	1-4 mg/day	Sedation, elevated serum prolactin, weight gain	Improvement in disruptive behavior based on ABC and CGI scores
Hellings *et al.* 2006	4-10 mg/day (Vanden Borre *et al.* 1993)		
Vanden Borre *et al.* 1993			
Zarcone *et al.* 2001			

Note. All RCTs had at least 10 participants/subjects. ABC = Aberrant Behavior Checklist; CGI = Clinical Global Impression Scale; EPS = extrapyramidal side effects; NCBRF = Nisonger Child Behavior Rating Form.

[a] Commonly reported side effects in studies. List is not comprehensive.

Other Medications

Medications such as SSRIs, naltrexone, buspirone, and anticonvulsants have also been examined in small, typically open-label studies of aggressive behaviors in IDD. While the evidence base is limited and derives mostly from decades-old investigations, the putatively more benign side-effect profiles of some of these agents warrant additional investigation in future research.

In an underpowered RCT (*n* = 8), clomipramine demonstrated significant reduction in frequency of SIBs (Lewis *et al.* 1996), although it did not separate from placebo, which also demonstrated a decrease in symptoms. Clomipramine was also found to reduce stereotypies and repetitive behaviors in a similar placebo-controlled, but again underpowered, RCT (Lewis *et al.* 1995).

Studies of SSRIs are quite mixed and generally lack rigorous study designs; one retrospective review found that paroxetine reduced SIBs but not aggression (Janowsky *et al.* 2005), while another demonstrated short-term improvements in aggression after 1 month, which were not sustained at 4-month follow-up (Davanzo *et al.* 1998). Improvement in SIBs was also noted with fluoxetine (Cook *et al.* 1992; Markowitz 1990) and sertraline (Hellings *et al.* 1996), although, again, these older studies were typically small and lacked a control arm. In contrast, other studies have demonstrated a mixed response to fluoxetine or paroxetine, or even a worsening of symptoms (Branford *et al.* 1998; Troisi *et al.* 1995). Despite the lack of large RCTs of SSRIs in the treatment of IDD, the relatively benign side-effect profile of SSRIs (relative to antipsychotics) indicates that empirical use of SSRIs, with careful titration and monitoring, may be of benefit in treating underlying anxiety or obsessive-compulsive symptoms (Sohanpal *et al.* 2007) as well as mood symptoms.

Mood-stabilizing medications may have a possible role in treating aggression and problem behaviors, with older controlled studies of lithium (Craft *et al.* 1987) and topiramate (Reid *et al.* 1981) demonstrating consistent improvements in target symptoms. Small retrospective studies similarly found reductions in aggression, SIBs, and challenging behaviors with lithium (Langee 1990), divalproex (Ruedrich *et al.* 1999), and topiramate (Janowsky *et al.* 2003b). Notably, individuals with IDD and comorbid epilepsy are often excluded from studies, despite the fact that seizure disorders are prevalent in this population. Interestingly, one retrospective study found decreased prescribing of antidepressants and anxiolytics for individuals with IDD who were taking antiepileptic drugs (Leunissen *et al.* 2011), although this was an observational study that requires additional investigation. Several placebo-controlled RCTs have also assessed naltrexone in IDD, with the smaller trials (4-8 participants) reporting some reduction in SIBs (Sandman *et al.* 1990, 2000; Symons *et al.* 2001; Thompson *et al.* 1994), while a larger study with 25 individuals with IDD reported no benefit; of note, this study included individuals with a milder range of symptoms (Willemsen-Swinkels *et al.* 1995).

Psychopharmacological Management of ADHD and Disruptive Behavior Disorders

Symptoms related to hyperactivity, impulsivity, and poor focus and attention are common presenting symptoms in IDD; however, most psychopharmacology research in ADHD routinely excludes children with IDD. Table 65-3 presents a summary of RCTs examining psychopharmacological treatment of disruptive behavior and ADHD in children with IDD.

TABLE 65-3. **Summary of randomized controlled trials (RCTs): psychopharmacological studies of disruptive behavior and ADHD in children with intellectual developmental disorder**

Medication/RCTs	Dosing range	Side effects	Outcomes
Methylphenidate			
Aman *et al.* 1991	0.3-1.5 mg/kg	Sleep problems with higher dosages	Aman *et al.* 1991: Improvement in specific metrics of behavioral tasks (Continuous Performance Test, matching-to-sample task, and short-term memory task)

Medication/RCTs	Dosing range	Side effects	Outcomes
Aman *et al.* 1993	Simonoff *et al.* 2013: individually titrated from 0.5 to 1.5 mg/kg	Poor appetite with higher dosages	Aman *et al.* 1993: Improvement in teacher ratings on CTRS and ABC; parent ratings showed improvement on RBPC, ABC, Real Life Rating Scale, and Global Rating Scales
Aman *et al.* 1997		Handen *et al.* 1999: Adverse side effects (including social withdrawal, crying, and irritability) noted in 5 of the 11 children in study	Aman *et al.* 1997: No improvements in parent ratings; teacher ratings showed significant improvement on ABC-Hyperactivity subscale and CTRS-Hyperactivity subscale
Aman *et al.* 2003			Aman *et al.* 2003: Improvement in teacher ratings on CTRS, ABC, and CASQ and in parent ratings

Medication/RCTs	Dosing range	Side effects	Outcomes
			on RBPC, ABC, and CASQ
Green *et al.* 2011[a]			Green *et al.* 2011: Improvement on CPRS-Revised
Hagerman *et al.* 1988			Hagerman *et al.* 1988: Teacher ratings showed improvement on ACTeRS Social Skills and Attention subscales; improvement on Conners' Abbreviated Parent-Teacher Questionnaire was not statistically significant
Handen *et al.* 1990			Handen *et al.* 1990, 1992: Improvement on CTRS and Child Attention Problems (CAP) Behavior Checklist
Handen *et al.* 1992			Handen *et al.* 1999: Improvement on CTRS and

Medication/RCTs	**Dosing range**	**Side effects**	**Outcomes**
			Preschool Behavior Questionnaire
Handen *et al.* 1999			Pearson *et al.* 2003: Significant improvements largely in teacher reports on CTRS and ACTeRS; parent report showed improvement only on CPRS Impulsive-Hyperactive subscale
Pearson *et al.* 2003			Simonoff *et al.* 2013: Improvement on CTRS, CPRS, and ABC
Simonoff *et al.* 2013			
Dextroamphetamine			
Hagerman *et al.* 1988[b]	0.2 mg/kg/day	Mood lability, irritability	Hagerman *et al.* 1988: Inconclusive--measures[b] demonstrated trends toward improvement but

Stimulant Medications

The largest RCT of methylphenidate among children with IDD (*N* = 122 participants ages 7-15 years who were not on already on medications) found methylphenidate to be effective in about 40% of children with an ICD-10 diagnosis of hyperkinetic disorder, with an effect size of 0.39-0.52 (Simonoff *et al.* 2013), which is consistent with findings in previous RCTs in youths with IDD (Aman *et al.* 2003; Pearson *et al.* 2003) but is lower than findings reported for typically developing children (Cortese *et al.* 2018). Methylphenidate's adverse effects in children with IDD and ADHD--primarily appetite suppression and sleep problems--were similar to those in typically developing children (Pearson *et al.* 2003; Simonoff *et al.* 2013). The smaller aggregated studies in the Aman *et al.* (2003) study suggest that lower IQ might predict poorer response to methylphenidate, but the larger Simonoff *et al.* (2013) study did not find the efficacy of methylphenidate to be moderated by IQ, presence of autistic symptoms, or severity of ADHD symptoms. This suggests that despite showing smaller effect sizes in IDD, methylphenidate can be considered an efficacious treatment for ADHD across levels of severity or ASD comorbidity. Notably, studies used primarily the immediate-release formulations of methylphenidate rather than the long-acting formulations more commonly used in current practice, and evidence on amphetamine derivatives was lacking (Thomson *et al.* 2009).

RCTs also have shown that risperidone reduces hyperactivity in children with IDD and DBDs (Aman *et al.* 2002; Snyder *et al.* 2002), although these were add-on trials and permitted ongoing stimulant medication in youths with ADHD (see Table 65-3). A post hoc analysis selecting patients with ADHD (rather than unspecified DBDs) suggested that adding risperidone to a stimulant led to improved control of hyperactivity compared with stimulant use alone. In a comparison study of risperidone and methylphenidate for treatment of ADHD, both medications were found to reduce inattention and hyperactivity, in addition to oppositional defiant disorder symptoms, with more pronounced effects for risperidone (Correia Filho *et al.* 2005). Finally, Handen and Hardan (2006) found improvement in hyperactivity with olanzapine, with concomitant stimulant use allowed. Despite the potential efficacy of atypical antipsychotics for the treatment of ADHD, methylphenidate remains the first-line agent because of its more benign side-effect profile (Correia Filho *et al.* 2005).

In contrast to findings in pediatric populations, evidence for stimulant use in adult patients with IDD is largely absent, although one retrospective chart review of 10 adult outpatients with IDD and ADHD who were treated with either amphetamine or methylphenidate found that 5 (50%) of the adults demonstrated improvement in symptoms, as assessed by decreases in scores on the CGI and on the Hyperactivity and Irritability subscales of the ABC (Jou *et al.* 2004).

Nonstimulant Medications

A large open-label prospective examination of atomoxetine (Fernandez-Jaen *et al.* 2013) in 24 patients with DSM-IV (American Psychiatric Association 1994) pervasive developmental disorder and symptoms of

ADHD found significant improvement in CGI, ADHD Rating Scale IV, and Conners Ratings Scale scores, although a separate retrospective chart review suggested that response in these populations may be less robust than that in typically developing peers (Mazzone *et al.* 2011).

a-Agonists have also been studied; an RCT of clonidine (Agarwal *et al.* 2001) for children with IDD and ADHD demonstrated significant benefit on parent and clinician ratings of hyperactivity, impulsivity, and inattention. Data for guanfacine are inconclusive, with one RCT (Handen *et al.* 2008) and one retrospective chart review (Posey *et al.* 2004) demonstrating improvements in some individuals with IDD and comorbid ASD, although lack of independent analyses for cohorts without ASD comorbidity prevented meaningful interpretation for IDD.

Pharmacological Management of Disordered Sleep

Persistent sleep problems have been reported at much higher rates in individuals with IDD than in the general population (Harper *et al.* 2023). Etiologies are likely heterogeneous, but sleep disorders have consistently been identified in individuals with idiopathic IDD (Esbensen and Schwichtenberg 2016) as well as those with specific genetic syndromes (Agar *et al.* 2021). A number of RCTs have examined the efficacy of melatonin for sleep disturbances in children (Appleton *et al.* 2012; Camfield *et al.* 1996; Coppola *et al.* 2004; Dodge and Wilson 2001; Wasdell *et al.* 2008) and adults (Braam *et al.* 2008) with IDD (Table 65-4). The majority of these studies confirmed the efficacy of melatonin at standard dosages in reducing sleep onset latency and duration of total sleep, although improvement in midcycle awakening was found only with adults. In contrast to the robust literature on melatonin, there are limited studies examining other pharmacological interventions for sleep in IDD, despite their wide prevalence of use (Bruni *et al.* 2018). Medications empirically used for sleep in IDD include the broad prescription of antihistamines, clonidine, benzodiazepines and other GABAergic agents, trazodone, mirtazapine, tricyclic antidepressants, and atypical antipsychotics, which have been comprehensively reviewed elsewhere (Bruni *et al.* 2018; Hollway and Aman 2011). Given the lack of rigorous evaluation of their use to improve sleep in IDD, it is difficult to assess the clinical efficacy of these agents; however, a small number of retrospective chart reviews and open-label studies suggested that some of these medications showed possible benefit for insomnia in children with IDD. These small studies included examinations of clonidine at dosages of 0.15-0.225 mg daily (Ingrassia and Turk 2005), mirtazapine at dosages of 7.5-45 mg daily in a cohort with mixed diagnoses and clinical outcomes (Posey *et al.* 2001), and gabapentin at dosages averaging 5-15 mg/kg (Robinson and Malow 2013). Although these medications warrant future study, in the absence of other evidence, mirtazapine, gabapentin, and trazodone may be considered for insomnia that does not respond to melatonin. Clonidine may also be considered as a potential intervention if there are no contraindications to its use, with careful monitoring for side effects.

TABLE 65-4. Summary of randomized controlled trials (RCTs): psychopharmacological studies of melatonin for disordered sleep in children and adults with intellectual developmental disorder

RCTs	Dosing range	Side effects	Outcomes	Comments

Note. All RCTs had at least 10 participants/subjects. ASD = autism spectrum disorder.

Psychopharmacological Management of Mood and Anxiety Disorders

Despite early literature suggesting lower rates of mood and anxiety disorders among individuals with IDD, more recent literature indicates that the prevalence of these disorders, including major depressive disorder and anxiety disorders (Cooper *et al.* 2007; Platt *et al.* 2019), is similar to or higher than that among individuals without IDD. Yet little research has directly examined the treatment of mood disorders, anxiety disorders, OCD, or PTSD in individuals with IDD, as evidenced by the absence of large RCTs and few open-label trials. This lack of studies again raises concern for underdiagnosis of mood and anxiety disorders in individuals with IDD, as well as raising additional questions about the frequent prescription of antipsychotics and mood stabilizers in this population, rather than antidepressant and antianxiety medication. While there is a broader literature examining the use of antipsychotics and mood stabilizers in the management of disruptive, self-injurious, and challenging behaviors (outlined earlier in this chapter) that may support the tolerability and potential efficacy of these medications for the treatment of bipolar disorder in this population, rigorous RCTs examining first-line treatments in IDD for unipolar depression and anxiety disorders (i.e., SSRIs and SNRIs) are sorely needed. In addition, several small open-label studies of SSRIs have reported positive effects on specific depression outcome measures in adults with IDD, including improvement in CGI ratings and remission over a year with citalopram (average dosage 20-40 mg/day) (Verhoeven *et al.* 2001) and reduction in Hamilton Rating Scale for Depression scores with fluoxetine (average dosage 20-40 mg/day) (Howland 1992). Paroxetine (average dosage 20-40 mg/day) was also found to reduce Montgomery-Asberg Depression Rating Scale scores in adolescents with mild IDD and comorbid major depressive disorder (Masi *et al.* 1997). Specific to OCD, one open-label study in adults found improvement in target symptoms with fluoxetine (40-80 mg/day) (Bodfish and Madison 1993), and another noted improvement with clomipramine (75 mg/day) (Barak *et al.* 1995). There is a dearth of research on well-defined bipolar disorder in this population, although small studies have indicated benefit from valproic acid in adults and adolescents (Kastner *et al.* 1993; King *et al.* 2000). Data for lithium and carbamazepine are limited to case reports, and outcomes are mixed (Vanstraelen and Tyrer 1999).

Given the lack of robust evidence, psychopharmacological approaches may be extrapolated from the broader literature in typically developing populations, with careful consideration for adverse side effects and judicious diagnostic consideration to avoid overdiagnosis of bipolar and psychotic disorders (Charlot *et al.* 2007). Additionally, RCTs of SSRIs, serotonin-norepinephrine reuptake inhibitors, and mirtazapine for the treatment of mood and anxiety disorders in individuals with IDD are much needed, especially because their long-term tolerability and favorable side-effect profiles make these medications good options.

Psychopharmacological Management of Schizophrenia and Schizoaffective Disorder

The prevalence of schizophrenia spectrum disorders is higher in individuals with IDD (2%-7%) relative to the general population (Deb *et al.* 2001; Cooper *et al.* 2007; Morgan *et al.* 2008). However, the extent to which this difference represents shared etiological factors, overdiagnosis, evidence of premorbid intellectual deficits in schizophrenia spectrum disorders, or intellectual decline associated with onset of schizophrenia in adulthood is still unclear. Regardless of etiology, prevalence rates do not appear to match with prescription practices; a recent UK study that analyzed treatment data for adults with IDD who had received antipsychotic medication for at least 1 year ($N = 977$) found that 24% of these individuals were prescribed this medication for a diagnosis of a schizophrenia spectrum disorder, a much higher rate than expected (Paton *et al.* 2022). When an accurate diagnosis of schizophrenia is determined, efficacy of antipsychotic usage specific to IDD is unknown (Duggan and Brylewski 1999), and decision-making relies largely on clinical judgments from the broader schizophrenia evidence base. One clinical consideration is that psychosis in individuals with IDD may be associated with greater symptom burden and more severe negative symptoms compared with psychosis in individuals with schizophrenia without IDD (Bouras *et al.* 2004). Additionally, careful consideration regarding seizure risk should be incorporated in treatment decision-making, particularly for medications such as clozapine (Ayub *et al.* 2015).

Recent Research in Genetic Syndromes

Routine clinical workup for newly diagnosed IDD should include referral for genetic testing (Muhle *et al.* 2017), because the diagnostic yield for specific genetic syndromes is increasing (Anazi *et al.* 2017). IDD is a nonexclusive diagnosis, which means that concurrent diagnoses of IDD and an identified genetic syndrome or medical condition associated with IDD (e.g., fragile X syndrome [FXS]) are appropriate. Given the expansion of genetic testing and identification of IDD-associated genes, it is expected that the cohort of identified genetic syndromes in IDD will increase in the coming years, although nonsyndromic etiologies continue to be the largest cohort in IDD at this time. Although this chapter has focused on idiopathic or nonsyndromic IDD, there are several studies on pharmacological approaches that may be appropriate for consideration in syndromic IDD, because individual genetic syndromes have specific behavioral phenotypes that may benefit from syndrome-specific intervention, including medication management. It would be difficult to comprehensively review the broader literature, but a few studies are highlighted here. Additionally, the putatively more homogeneous etiologies underlying IDD in these syndromes may provide important mechanistic insights into IDD symptoms and behaviors more broadly.

Fragile X Syndrome

The bulk of pharmacological research on genetic syndromes in IDD exists in the FXS literature. FXS is the most common inherited cause of IDD, resulting from a trinucleotide repeat in the *FMR1* promoter region, occurring in about 1 in 7,000 boys and 1 in 11,000 girls (Hunter *et al.* 2014). Comorbid psychiatric conditions are commonly associated with FXS, including ASD, anxiety, inattention, hyperactivity, irritability, and aggression. Unsurprisingly, the medications prescribed for management of these symptoms are similar to those prescribed in idiopathic IDD, including SSRIs, psychostimulants, and atypical antipsychotics, with generally positive response rates for target symptoms (Dominick *et al.* 2021; Erickson *et al.* 2011). Specific to FXS, neurobiological treatment targets have focused on metabotropic glutamate and GABA receptors, based on downstream effects of the FMR protein. However, despite promising drug investigations in animal studies, similar studies in human clinical trials targeting these pathways have generally not yielded positive results in primary outcomes, although this remains a robust area of ongoing research (Berry-Kravis *et al.* 2018; Hagerman *et al.* 2017). Also, a large RCT was conducted with minocycline for children with FXS, demonstrating improvement in CGI and mood and anxiety scores (Leigh *et al.* 2013). Targeting aberrant Ras/MAPK activity in FXS, both a small, open-label

trial of lovastatin (Caku *et al.* 2014) and a combination RCT of minocycline and lovastatin (Champigny *et al.* 2022) demonstrated improvements in ABC Community scores. Also, small case studies (Biag *et al.* 2019; Dy *et al.* 2018; Protic *et al.* 2019) and an open-label trial (Proteau-Lemieux *et al.* 2021) have suggested potential benefit with metformin. Transdermal cannabidiol in a cohort of 20 youths with FXS and anxiety demonstrated decreases on the Anxiety, Depression and Mood Scale over a 12-week period (Heussler *et al.* 2019), although IQ was not included in demographic data or inclusion criteria. Data on nutraceuticals, such as folic acid and L-acetylcarnitine, are equivocal in human studies (Rueda *et al.* 2011, 2015).

Other Genetic Syndromes

Rigorous placebo-controlled studies specific to other genetic syndromes associated with IDD are also lacking. Again, pharmacological approaches largely approximate approaches in idiopathic IDD (Butler *et al.* 2006; Palumbo and McDougle 2018; Sabus *et al.* 2019). Here, selective reviews of medication trials in syndromes are highlighted, as well as some discussion of drug development that may have potential future impact on IDD more broadly.

In Down syndrome, for example, acetylcholinesterase inhibitors have been studied as a potential intervention for dementia in older individuals with Down syndrome and in RCTs in children and adolescents (Kishnani *et al.* 2010; Spiridigliozzi *et al.* 2016). Unfortunately, results did not show a significant impact on cognitive, language, and adaptive functioning, but treatment was well tolerated. As in nonsyndromic IDD, low dosages of guanfacine were found to reduce hyperactivity and irritability symptoms in children with Down syndrome and comorbid ADHD, the majority of whom were not taking stimulants (Capone *et al.* 2016).

In Rett syndrome, recent research has focused on clinical trials of trofinetide, a synthetic insulin-like growth factor analog that has shown promising results based on CGI and Rett Syndrome Behavior Questionnaire scores (Glaze *et al.* 2019), including recent positive industry-funded Phase III trial outcomes (Neul *et al.* 2023). Based on these studies, trofinetide received FDA approval in March 2023 for the treatment of Rett syndrome in adults and pediatric patients ages 2 years and older. Trofinetide and similar agents are preliminarily being assessed in other conditions, such as FXS.

An RCT in Prader-Willi syndrome targeting perseverative eating behaviors demonstrated reductions in hyperphagia with topiramate (Consoli *et al.* 2019), although no between-group differences were found in CGI scores. Several recent RCTs of oxytocin administration in Prader-Willi syndrome have also shown improvements in mood and in social and eating behaviors (Damen *et al.* 2021; Kuppens *et al.* 2016; Miller *et al.* 2017). Open-label studies have also suggested potential limited benefit of *N*-acetylcysteine in skin-picking behaviors in Prader-Willi syndrome (Miller and Angulo 2014; Wieting *et al.* 2022).

Although studies in syndromic IDD are limited and there is still incomplete understanding of how pharmacological interventions may be extrapolated from one condition to another, the mechanistic models for aberrant neurodevelopment in syndromic IDD may also provide a model for hypothesis-driven approaches to drug development for idiopathic IDD more broadly. A road map for translational research initiatives that may lead to innovation in IDD treatment is sorely needed (Markati *et al.* 2021; Vashi and Justice 2019) and would fill a critical gap in treatment development for nonsyndromic IDD.

Medication Side-Effect Profiles

Until disease-modifying treatments are available, treatment of comorbid or nonspecific symptoms remains the primary clinical intervention in IDD. With this in mind, addition of medications requires thoughtful and ongoing evaluation for actual benefit for target symptoms balanced against vigilant monitoring for adverse side effects. Careful attention to side effects is particularly relevant in IDD, where complex cases often result in substantial polypharmacy, further increasing the potential risk of drug-drug interaction effects and adverse events. A recent cross-sectional study of youth and adolescents with IDD ($N = 1{,}333$; ages 5-21 years; included youth with ASD) found that more than 86% of the sample received psychotropic medications, and more than half were on three or more psychotropics (McLaren *et al.* 2021).

Reducing the likelihood of adverse side effects and identifying them when they do manifest are especially important for vulnerable IDD cohorts; this is particularly true for individuals with limited communication, placement in living environments with less supervision, decreased ability to self-advocate, or limited access to appropriate specialized care. For example, sedating and cognitive impairment effects should be considered in pharmacological treatment selection for individuals with baseline cognitive deficits, as may occur with anticholinergic and antihistaminergic agents. Concern for long-term weight gain should also be considered when starting antipsychotics, especially given evidence of challenges in regular monitoring of metabolic side effects on an ongoing basis (Teeluckdharry *et al.* 2013). Indeed, logistical challenges, such as difficulty obtaining labs, may also be a consideration for medications that require frequent monitoring (e.g., clozapine, lithium). Similarly, as epilepsy is overrepresented in IDD, agents lowering the seizure threshold may be inadvisable--although, conversely, use of mood stabilizers or antiepileptic drugs may present an opportunity for parsimonious treatment decisions given their dual clinical functions.

While the increased representation of adverse side effects in IDD is probably due to both direct and indirect mechanisms, these effects do appear to be observed at higher rates than would be expected in comparable populations. Common side effects with higher-than-expected rates in individuals with IDD include gynecomastia, EPS, hyperprolactinemia, hypercholesterolemia, and akathisia (Ballester *et al.* 2022; Charlot *et al.* 2020; Sheehan *et al.* 2017). Clinical signs of EPS in this population may include staring, flat facial expression, prolonged response latency, odd facial grimacing, tremors, and muscle stiffness, which clinicians may mistake for features of IDD (i.e. diagnostic overshadowing), thereby missing serious medication side effects. For example, akathisia may be mistaken for an increase in impulsivity, agitation, or restlessness, especially in an individual with limited language to share internalizing experiences, possibly leading to an increase in medications rather than the needed dosage tapering. Rates of serious adverse side effects with antipsychotic medication are also increased in this population; for example, antipsychotic-related neuroleptic malignant syndrome is three times more common in adults with IDD than in control subjects without IDD (Sheehan *et al.* 2017).

Therefore, de-prescription practices are particularly relevant in pharmacological management of IDD, because it is a pervasive, lifelong condition. Indeed, it is not uncommon for individuals with IDD to accumulate multiple psychotropic medications over years of treatment. Rigorous approaches to de-prescription can be drawn from parallels in other cohorts, such as medication management in older adults (Scott *et al.* 2015), and have been modeled in health systems in other countries where treatment philosophies for individuals with IDD focus more heavily on wraparound services and minimization of antipsychotic use to control aggression (Granas *et al.* 2019; Shankar *et al.* 2019a). Generally, deprescribing should follow rational risk-benefit assessment at regular intervals during treatment of individuals with IDD (Scott *et al.* 2015; Shankar *et al.* 2019b), via an interdisciplinary approach incorporating all stakeholders, particularly caretakers of the individuals with IDD (Ahmed *et al.* 2000; de Kuijper and Hoekstra 2018).

Conclusion

The research base for pharmacological intervention in IDD is limited. Careful diagnosis and identification of specific treatment targets are needed in this vulnerable population. When present, specific comorbid diagnoses should be treated, often with pharmacological interventions for anxiety, mood disorders, ADHD, and psychosis similar to those used with non-IDD cohorts. Nonspecific diagnoses, such as challenging or problem behaviors, remain a common presentation in IDD, and atypical antipsychotics are often prescribed for these symptoms. However, the existing evidence indicates that these medications confer only modest benefits and often carry a substantial side-effect burden, highlighting the need for comprehensive, multimodal approaches in IDD that encompass behavioral and systems-of-care interventions rather than relying on pharmacotherapy alone. Therefore, treatment selection in IDD requires rational assessment of the need for each medication weighed against potential drug-induced harm, with ongoing careful monitoring of actual benefit and potential adverse side effects. Given the long-term nature of IDD, comorbid symptoms and behaviors should be routinely assessed, and de-prescription of medication for these symptoms should be considered at regular intervals in the treatment process.

CHAPTER 66

Treatment of Autism Spectrum Disorder

John P. Hegarty II, Ph.D.
Antonio Y. Hardan, M.D.

Autism spectrum disorder (ASD) is a neurodevelopmental disorder characterized by persistent challenges in social communication and social interaction and the presence of a range of sensory processing differences and restricted and repetitive behaviors (RRB). As outlined in DSM-5 (American Psychiatric Association 2013) and ICD-11 (World Health Organization 2018), ASD symptoms must present early in life but may be masked or not fully manifest until demands exceed a child's capacity or learned strategies. The core social communication impairments (SCI) and RRB symptoms of ASD are usually pervasive and observable across multiple settings, with some variation depending on context, and must be severe enough to cause clinically significant impairments in personal, social, educational, occupational, or other important areas of functioning for the child to meet diagnostic criteria. Autistic individuals may or may not also exhibit additional cognitive and behavioral challenges, such as intellectual developmental disorders, adaptive skill deficits, language delay, or a multitude of other comorbid psychiatric symptoms and medical issues, including anxiety, depression, attentional problems, epilepsy, sleep disturbances, and gastrointestinal issues. Recent prevalence rates for ASD range from 1 in 36 children in the United States (Maenner *et al.* 2023) to approximately 1 in 161 individuals worldwide (Elsabbagh *et al.* 2012), with an estimated yearly economic cost of up to $1 trillion just in the United States (Leigh and Du 2015). Although ASD is a pervasive developmental disorder, our understanding of its underlying pathophysiology is still very incomplete, and there are currently no biologically based pharmacological interventions for targeting the core symptom domains. Behavioral therapy is typically the first-line treatment for patients with ASD, and pharmacological interventions are currently directed at the management of comorbid psychiatric and medical conditions, with the primary goal of improving functioning in daily activities.

This chapter will review the history of drug trials in patients with ASD, discuss current clinical practices and novel agents that are under investigation, and outline recommendations and future directions for targeting the core symptom domains.

Brief History of Drug Trials in Autism Spectrum Disorder

Failed Randomized, Placebo-Controlled Trials for Core Symptoms

Serotonergic Agents

Shortly after the first descriptions of autistic patients by Leo Kanner (Kanner 1943) and Hans Asperger (Asperger 1944), research to elucidate the biochemical basis of the disorder began. One of the earliest studies examined whole blood levels of serotonin and reported that 6 of 23 patients with "infantile autism" were well outside the normal range (Schain and Freedman 1961). Subsequent studies of the potential role of serotonin in autism have reported mixed results, yet a recent meta-analysis indicated that both whole blood and platelet-rich plasma levels are consistently elevated in approximately 25% of individuals diagnosed with ASD (Gabriele *et al.* 2014). Following these initial reports, small-scale trials investigating the potential efficacy of serotonergic drugs, particularly selective serotonin reuptake inhibitors (SSRIs) for targeting RRB, were initiated because SSRIs were previously shown to be effective for targeting compulsive and repetitive behaviors in other disorders such as OCD (Soomro *et al.* 2008). To date, the small number of randomized controlled trials (RCTs) that have been completed in patients with ASD indicate some potential benefits for adults, while findings in youth are inconsistent (Williams *et al.* 2013). Nonetheless, serotonergic drugs remain "a prime candidate for treatment development" in children and adults with ASD (Muller *et al.* 2016), and serotonergic biomarkers may aid in the identification of patients most likely to respond to SSRIs.

Dopaminergic Agents

In addition to SSRIs, dopaminergic agents have also received considerable attention in ASD. Autism was initially conceptualized as a childhood form of schizophrenia, in which dopaminergic dysfunction is postulated to play a central role. A dopamine hypothesis has also been proposed as a primary mechanism in ASD (Paval 2017), with both hypo-dopaminergic (Ernst *et al.* 1997) and hyper-dopaminergic (Nakamura *et al.* 2010) activity being reported. First-line treatments for schizophrenia (e.g., typical antipsychotics such as haloperidol) have high affinity for D_2 receptors and were some of the earliest pharmacological treatments that were examined for ASD. They exhibited some initial promise for targeting global improvements in emotion regulation and maladaptive behaviors, as well as some other behaviors associated with the core symptom domains (Anderson *et al.* 1984; Faretra *et al.* 1970). Further research then indicated that atypical antipsychotics may be even more effective than typical antipsychotic agents for children with ASD (Miral *et al.* 2008). However, typical and atypical antipsychotics can lead to some severe side effects in children and adolescents, including significant weight gain and tardive dyskinesia, and they are not selective for dopamine receptors. Thus, increased monitoring is necessary when antipsychotics are administered to autistic patients, and additional research will be necessary to elucidate the potential role of dopamine in the pathophysiology of the disorder, especially as it relates to treatment response and the development of more targeted interventions. Currently, the only approved drugs for use in children and adolescents with ASD are the atypical antipsychotics risperidone and aripiprazole. They are discussed in more detail later in this chapter.

Glutamatergic and GABAergic Agents

Another prominent theory regarding the pathophysiology of ASD posits that an imbalance between excitatory and inhibitory signaling underlies the core symptom presentation (Hussman 2001; Rubenstein and Merzenich 2003), specifically an increased ratio of excitation to inhibition in key neural circuits in the brain. Both glutamatergic (Moreno-Fuenmayor *et al.* 1996) and GABAergic (Dhossche *et al.* 2002) dysfunction have been implicated in ASD, but as with dopaminergic alterations, there are mixed reports regarding the specific signaling pathways and brain circuits (Fung *et al.* 2021;

Hegarty *et al.* 2018a, 2018b). Patient responses to GABAergic (Brondino *et al.* 2016) and glutamatergic (Rojas 2014) drugs are also mixed, which may be partially related to developmental changes in these systems over time and the extreme neurobiological heterogeneity across affected individuals. Early investigations suggested that glutamatergic (e.g., memantine) and GABAergic (e.g., arbaclofen) agents may provide some therapeutic effects in patients with ASD (Chez *et al.* 2007; Erickson *et al.* 2014), but the primary outcome measures on subsequent RCTs failed to replicate these early findings (Aman *et al.* 2017; Veenstra-VanderWeele *et al.* 2017). Secondary analyses of these data indicate that additional investigation may be warranted.

Other Miscellaneous Interventions

Anecdotal evidence supports a wide array of alternative therapies for targeting both core and comorbid psychiatric symptoms in children with ASD, including dietary restrictions, nutritional supplements, hyperbaric oxygen therapies, acupuncture, and massage (Brondino *et al.* 2015). Support for most of these treatments is based largely on parent reports of individual patients, case series, and open-label trials, with empirical evidence from RCTs either lacking or inconclusive. For instance, Horvath *et al.* (1998) reported in a case series that three autistic children who were given secretin for a clinical endoscopy, a hormone that regulates water homeostasis and secretions in the stomach, pancreas, and liver, exhibited improved eye contact, alertness, and expressive language after infusion (Horvath *et al.* 1998). Secretin then received considerable media coverage and interest from parents and patients that resulted in significant off-label use. Unfortunately, RCTs of secretin failed to support these initial reports, and their results indicated that secretin was unlikely to provide any cognitive or behavioral benefits for children with ASD (Sandler *et al.* 1999; Sturmey 2005). Although secretin did not benefit the core symptom domains, it did help spur investigations into the potential role of gastrointestinal disturbances in the disorder, which are common in autistic patients and a salient treatment target for some individuals (McElhanon *et al.* 2014). Alternative therapies can be attractive treatment options for parents and patients if they are generally safe and well tolerated and could potentially provide some clinical benefits, but additional RCTs will be necessary before clinicians can recommend widespread use.

Issues That Contribute to Failed RCTs

Case studies and pilot trials have reported potential efficacy for a wide array of pharmacological interventions for symptoms of ASD, but there are currently no drugs approved by the FDA or European Medicines Evaluation Agency (EMA) for targeting the core SCI and RRB. Some trials in patients with ASD fail simply because of a lack of efficacy of the investigational drug for the target symptom. However, a significant proportion of these trials may also fail due to the extreme phenotypic and biological heterogeneity across autistic individuals, changes in treatment response over different developmental periods, high levels of placebo response, increased incidence of psychiatric and medical comorbidities in the ASD population, and poor psychometric properties and sensitivity to change of the available outcome measures for assessing treatment-related change. Therefore, innovative approaches are needed, such as adaptive clinical trial designs--including sequential parallel comparison design (Fava *et al.* 2003) and its more recent extension, two-way enrichment design (Ivanova and Tamura 2015)--that aim to reduce the placebo response. Furthermore, novel platform designs (Berry *et al.* 2015) such as Leapfrog that test multiple interventions and use statistical analyses to remove poorly performing arms (Blackwell *et al.* 2019) will be necessary to account for and address the complicating and confounding factors encountered in ASD trials and will be critical for advancing the development of new pharmacological treatments for the core features, associated behaviors, and comorbid mental health disorders in this patient population.

Heterogeneity and Changes in Treatment Response Over Development

A major factor that modulates treatment response in children with ASD is the extreme heterogeneity of the disorder in terms of its pathophysiology and clinical phenotype (Jeste and Geschwind 2014; Masi *et al.* 2017), which has been well documented in the literature. First and foremost, up to 25% of cases of ASD are associated with various rare genetic and copy number variants, yet even the most prevalent individual genetic alteration is associated with only about 1% of cases. Therefore, most ASD cases probably originate from complex interactions between common multifactorial genetic variation and environmental factors (Miles 2011). These extreme differences in genetic and environmental contributions to the disorder are also reflected in the associated neurobiology (Hegarty *et al.* 2019, 2020a, 2020b), with significant alterations in brain structure, circuits, and neurochemical profiles across individuals (Amaral *et al.* 2008; McDougle *et al.* 2005a). Children and adults with ASD also display significant differences in symptom presentation across the core and comorbid psychiatric domains and exhibit a wide array of associated health and medical considerations. Developmental changes in cognitive, behavioral, and neurobiological profiles may also alter treatment response over time (Courchesne *et al.* 2011; Eaves and Ho 1996). Differences in response to fluoxetine are a prominent example of the effects that this neurobiological heterogeneity and developmental changes over time can have on treatment outcomes. For instance, most studies of fluoxetine in adults with ASD report significantly greater changes in RRB symptom severity with fluoxetine than with placebo, at least in the proportion of responders (~35%-50%) (Hollander *et al.* 2012; McDougle *et al.* 1996), whereas findings in children and adolescents are mixed (Herscu *et al.* 2020; Hollander *et al.* 2005), such that the current literature does not support widespread use of fluoxetine for children or adolescents with ASD. Fluoxetine might be beneficial for some autistic adults, but larger-scale RCTs will be necessary. Clinical research has also indicated that only about 25% of individuals with ASD exhibit hyperserotonergia, suggesting that only a proportion may respond to SSRIs. Differences in treatment response to SSRIs may also be related to genes associated with the serotonin transporter system that are altered in only a subset of the population (Sugie *et al.* 2005).

Increased Vulnerability to Side Effects

Children and adults with ASD have a high likelihood of exhibiting symptoms associated with other psychiatric disorders, especially anxiety and ADHD, and a wide array of medical and health considerations, including gastrointestinal disorders, seizures, and diabetes (Croen *et al.* 2015; Simonoff *et al.* 2008). These comorbid psychiatric, neurological, and medical conditions can create significant problems for treatment-related research because they may confer increased vulnerability to side effects from the investigational agents (McCracken 2005). For instance, studies investigating the use of methylphenidate to target symptoms of ADHD in children with ASD reported higher rates of "intolerable adverse events" (~30%) (Research Units on Pediatric Psychopharmacology Autism Network 2005) than were reported for children with ADHD only (~10%) (Wigal *et al.* 2006). Research studies have addressed this issue by excluding participants with comorbid diagnoses or using an initial dosage escalation phase to identify and exclude any participants who are not likely to respond (Sturman *et al.* 2017), but increased vulnerability to the study agents can still reduce retention of the remaining study participants. More importantly, knowledge of this increased vulnerability to certain agents alters the benefit-to-risk ratio of these agents for certain patients and may necessitate increased clinical monitoring, with regular evaluation across developmental periods.

Limitations of Primary Outcome Measures

One of the most important aspects of clinical trial design is the selection of reliable and valid outcome measures that are sensitive to treatment-related change. Objective biological markers have been identified for many medical and neurological disorders, but psychiatric research still relies heavily on subjective parent and clinician rating scales. The appendix table at the end of this chapter lists the clinical scales commonly used to monitor symptom severity in patients with ASD. To date, the assessment instruments used to measure changes in core symptom severity in clinical trials for ASD have been extremely variable across investigations, as have the psychometric properties associated with these instruments. Attempts have been made to identify the most appropriate outcome measures for trials targeting the core symptoms of ASD (Anagnostou *et al.* 2015; Scahill et al. 2015a), but there continue to be significant limitations in even the most commonly used and recommended measures. Therefore, efforts are ongoing to improve existing scales through use of factor analysis (Frazier *et al.* 2014; Sturm *et al.* 2022; Uljarevic *et al.* 2021; Zheng *et al.* 2021) and to design new scales with better construct validity and reliability (Phillips *et al.* 2019; Uljarevic *et al.* 2023). The development of more objective biological and surrogate outcome markers will also be critical for advancing pharmacological treatments for patients with ASD. Research into behavioral, physiological, and biological outcomes has already begun to report promising preliminary results (Ecker and Murphy 2014; Webb *et al.* 2020).

FDA-and EMA-Approved Treatments

Atypical Antipsychotics

The only pharmacological interventions currently approved by the FDA for use in children and adolescents with ASD are the atypical antipsychotics aripiprazole (Marcus *et al.* 2009; Owen *et al.* 2009) and risperidone (Hardan *et al.* 1996; McCracken *et al.* 2002; Sharma and Shaw 2012); however, these agents are not indicated for targeting the core symptom domains. Instead, they are used to treat symptoms of emotion dysregulation, such as severe irritability and aggression, that are associated with behavioral challenges in 20%-50% of autistic children (Lecavalier 2006; Samson *et al.* 2014), including self-injurious behaviors. Risperidone is also approved by the EMA for persistent aggression in conduct disorder in children. The target dosage for risperidone is about 1.6 mg/day (0.3-3.5 mg) and for aripiprazole is typically 5-15 mg/day. RCTs of risperidone reported greater decreases in irritability, aggression, tantrums, and self-injurious behaviors in autistic patients ages 5-17 years compared with placebo. Similarly, RCTs of aripiprazole also reported decreased irritability and some secondary effects on stereotypy, hyperactivity, and inappropriate speech, but these secondary targets still require replication in independent studies. These two atypical antipsychotics also appear to be superior to typical antipsychotics, such as haloperidol (Miral *et al.* 2008), as well as many other agents in terms of both efficacy and safety (Fung *et al.* 2016). Thus, risperidone and aripiprazole may provide some benefits in emotion regulation and help reduce some challenging or self-injurious behaviors, but it is important to implement increased monitoring for side effects because these agents are also associated with considerable adverse events, including nausea, dizziness, insomnia, increased appetite, significant weight gain, and extrapyramidal side effects (EPS) such as tardive dyskinesia.

Melatonin

Sleep disturbances are very common in children with ASD, with parent-reported sleep problems in up to 80% of autistic individuals (Couturier *et al.* 2005; Polimeni *et al.* 2005). These sleep problems are also associated with increased attentional, learning, and behavioral challenges during the day, including more severe irritability and aggression, which can be a primary source of stress for parents and caregivers and distress for patients. Meanwhile, improving sleep health with melatonin supplementation can reduce these challenging behaviors and improve overall quality of life (Schroder *et al.* 2019). Melatonin is commonly used over the counter to address sleep disturbances, and RCTs support traditional anecdotal evidence with reports of reduced time to sleep onset and increased sleep duration compared with placebo (Garstang and Wallis 2006; Rossignol and Frye 2011; Wright *et al.* 2011). Most studies evaluating melatonin (~1-10 mg) for targeting sleep in patients with ASD also report better sleep health and improved daytime behaviors with only minor side effects (e.g., morning drowsiness). New prolonged-release formulations (Circadin for adults and Slenyto for pediatric patients) have received considerable interest for improving sleep health in ASD (Gringras *et al.* 2017; Schroder *et al.* 2019). Slenyto is currently approved by the EMA for this purpose, but a clinical trial that was scheduled to begin in the United States in 2020 (NCT04233502) was canceled and withdrawn from ClinicalTrials.Gov.

Pharmacological Treatments for Specific Symptom Domains

Inattention

Before DSM-5, a diagnosis of ASD would preclude a patient from being diagnosed with ADHD (Antshel and Russo 2019), even when there were co-occurring symptoms. Comorbid diagnoses of ADHD and ASD are now common (Doernberg and Hollander 2016), with an approximate overlap of 30%-70%, yet pharmacological management of inattention and hyperactivity symptoms remains fundamentally the same for patients with a single or a dual diagnosis. Stimulants, such as methylphenidate, are the typical first-line treatment (Mahajan *et al.* 2012). However, there is only preliminary and limited evidence that methylphenidate reduces hyperactivity or inattention in children with ASD (Sturman *et al.* 2017). For instance, only about 50% of individuals with ASD may respond to methylphenidate treatment (Research Units on Pediatric Psychopharmacology Autism Network 2005), as opposed to approximately 80% of children with ADHD without concomitant ASD (Schachter *et al.* 2001). Children with ASD may also be more likely to exhibit "intolerable adverse events" during methylphenidate treatment. Thus, more conservative treatment approaches such as behavioral or environmental interventions should be explored before pharmacological therapy is initiated (McGuire *et al.* 2016). In cases where methylphenidate may be appropriate, children ages 6 years and older are typically prescribed 5 mg orally twice per day, before breakfast and lunch ("Methylphenidate" 2021; Sturman *et al.* 2017). A third dose before 6:00 P.M. can also be added, or an extended-release variant may be considered. Adults are typically prescribed 20-30 mg/day in two or three doses before meals.

In cases that are refractory to management with stimulants, alternative medications such as noradrenergic reuptake inhibitors (e.g., atomoxetine) or a_2-adrenergic agonists (e.g., clonidine or guanfacine) may be considered. However, the data pertaining to these medications are also limited in the context of ASD, and they should be trialed only as second-line pharmacological options (Banas and Sawchuk 2020; Ghanizadeh 2013; Scahill *et al.* 2015b). The following dosing recommendations were developed specifically for children with ADHD and will warrant further study in children with ASD. Atomoxetine may be prescribed to patients above the age of 6. If

they weigh 70 kg or less, the initial dosage should be 0.5 mg/kg/day, which can be increased after a minimum of 3 days to 1.2 mg/kg/day, up to a maximum of 1.4 mg/kg/day or 100 mg/day, whichever is less. Higher dosages can be considered if benefits were observed at lower dosages and no severe adverse effects events are reported. For patients above 70 kg, the initial dosage of 40 mg/day may be increased to 80 mg/day as tolerated. After another 2-4 weeks, the dosage can be further increased up to 100 mg/day ("Atomoxetine" 2021). Guanfacine is usually initiated at 1 mg/day and increased on a weekly basis by 0.5-1.0 mg, up to a maximum of 4 mg/day when well tolerated. Clonidine is generally prescribed to patients above the age of 6 years starting at 0.05 mg/day and is generally titrated up from an initial nightly dose to up to 4 times a day (Markram and Markram 2010). There is also some evidence that risperidone may reduce some symptoms of hyperactivity in children with ASD (Huffman *et al.* 2011; McCracken *et al.* 2002), but the benefit-to-risk ratio is rarely favorable for this use. When considering the best pharmacological approach for ADHD symptoms in autistic patients, it is imperative to consider all the various risks and benefits of each potential treatment. Methylphenidate and other stimulants are substances with addictive potential, a_2-adrenergic agonists can induce orthostatic hypotension, and antipsychotics have well-known adverse effects including weight gain and tardive dyskinesia.

Depression and Anxiety

Lifetime prevalence estimates of depression and anxiety in individuals with ASD range up to about 80% (Billstedt *et al.* 2005; Joshi *et al.* 2013; Nimmo-Smith *et al.* 2020; Vasa and Mazurek 2015), with meta-analyses indicating approximately 40% on average, and these estimates are at least two to three times higher than those for peers without ASD (Hollocks *et al.* 2019). Thus, the identification of depression and anxiety in patients with ASD is extremely important for their clinical care, but accurately identifying these symptoms can be difficult because cognitive and behavioral differences may lead to atypical symptom presentation, especially for nonspeaking or minimally verbal individuals or those who need a high level of support. As with most mood disorders, pharmacological therapy may be indicated in cases that are refractory to cognitive and behavioral intervention or for patients who exhibit a limited response. In patients without neurodevelopmental disorders, the guidelines for first-line medications are well supported (Bandelow *et al.* 2017; Karyotaki *et al.* 2016) and primarily include SSRIs and serotonin and norepinephrine reuptake inhibitors (SNRIs). However, there is not yet sufficient evidence to support any specific guidelines regarding the use of SSRIs or SNRIs for treating depression or anxiety symptoms in individuals with ASD (Chandrasekhar and Sikich 2015; Menezes *et al.* 2020; Williams *et al.* 2013). Despite these limitations, SSRIs are still frequently prescribed (Mandell *et al.* 2008; Menezes *et al.* 2020). For instance, fluoxetine can be initiated orally (PO) in children 8 years and older at 10 mg/day to target depression. The dosage can be increased after 1 or more weeks to 20 mg/day in children and adolescents and as much as 60-80 mg/day in adults ("Fluoxetine" 2021). Escitalopram is also commonly used in children ages 7 years and older at 10-20 mg/day to target depression, initiated at 10 mg/day and increased if necessary after at least 3 weeks in children and 1 week in adults ("Escitalopram" 2021). There are also several reports describing the use of these SSRIs for anxiety (Vasa *et al.* 2014). Atypical antidepressants and anxiolytics as well as other second-line pharmacological substances, such as mirtazapine and buspirone (Chugani *et al.* 2016; Posey *et al.* 2001), also have some limited evidence, but guidelines for these agents in patients with ASD also require further study.

Research examining the presentation and treatment of depression and anxiety in patients with ASD is especially important in light of the high rate of nonsuicidal self-injury and suicidal behavior in this population. Rates have been reported to be greater than 50% for suicidal ideation and greater than 30% for suicide attempts, such that individuals with ASD may account for more than 10% of the overall suicidal population (Hedley and Uljarevic 2018; Segers and Rawana 2014). This equates to individuals with ASD being up to six times more likely to attempt suicide and seven times more likely to die by suicide compared with the general population (Chen *et al.* 2017; Hirvikoski *et al.* 2016; Kirby *et al.* 2019). Suicide is such a critical issue for people with ASD that the International Society for Autism Research recently released a policy brief calling attention to this "hidden crisis." Suicide attempts may also be more common in individuals with more severe symptoms (Hand *et al.* 2020; Hedley and Uljarevic 2018; Pelton and Cassidy 2017) or intellectual developmental disorders, and individuals with difficulties in communication or expression of internal emotional states may be more likely to progress from suicidal ideation to actual suicide attempts. Additionally, autistic women appear to be especially vulnerable and may be more than 13 times more likely to die by suicide compared with nonautistic women (Hirvikoski *et al.* 2016). Thus, it is possible that suicidal thoughts and behaviors may have a different pathophysiology in some individuals with ASD compared with the general population, and conventional prevention strategies may not be as effective (Cassidy *et al.* 2018). The Safety Planning Intervention developed by Stanley and Brown (2012) is one evidence-based prevention approach for targeting suicide that has the potential to help people with ASD who are experiencing suicidal thoughts or behaviors. Most importantly, this intervention was recently adapted for individuals with ASD and is available online free of charge (Cassidy 2019). Furthermore, this adaptation is currently being investigated as a prevention procedure specifically designed for and validated in autistic adults (Rodgers *et al.* 2023).

Restricted and Repetitive Behaviors, Obsessive-Compulsive Behaviors, and Tics

Autistic people exhibit a wide range of repetitive, obsessive, and motor behaviors. The core RRB symptoms of ASD include repetitive motor behaviors (stereotypies), insistence on sameness, self-injurious behaviors, obsessive-compulsive behaviors, and circumscribed interests. Tics are also observed in ASD and consist of sudden twitches, movements, or sounds that individuals produce repeatedly. Although RRB is a diagnostic criterion of ASD, it is important to note that OCD and tic disorders are not, even though OCD and tic disorders are reported more frequently in patients with ASD than in the general population (Burd *et al.* 2009; Freeman *et al.* 2000; Meier *et al.* 2015). As with most therapeutic algorithms pertaining to ASD, nonpharmacological interventions should be trialed first, before the initiation of medication. SSRIs have been used to target RRB in adults with ASD (Hollander *et al.* 2012; McDougle *et al.* 1996), especially since it has been postulated that anxiety may worsen some of these symptoms (Postorino *et al.* 2017), but these medications were generally no better than placebo in large-scale

studies, including fluoxetine (Herscu *et al.* 2020) and citalopram (King *et al.* 2009). Overall, the current literature does not support widespread use of SSRIs for targeting RRB symptoms in children and adolescents with ASD. Larger-scale studies are warranted, but they will require the use of novel measures with good psychometric properties so that researchers can capture all of the relevant RRB subdomains (see the appendix table at the end of this chapter). Tricyclic antidepressants such as clomipramine, which is beneficial for OCD, have also been examined in ASD (Pittenger and Bloch 2014), but results are also inconsistent (Hurwitz *et al.* 2012), and the associated side effects, including cardiotoxicity and severe anticholinergic effects, render this alternative less desirable. Medications that are approved for treating irritability and emotion dysregulation in ASD (e.g., risperidone and aripiprazole) have shown some potential for targeting RRB in ASD as well (McDougle *et al.* 2005b). Although their side-effect profiles limit their applications for many types of RRB, they have shown some efficacy and are approved for targeting very severe RRB-like self-injurious behaviors, which are extremely important therapeutic targets that appear in almost half (~42% on average) of autistic patients (Steenfeldt-Kristensen *et al.* 2020). Finally, with regard to tic disorders, atypical antipsychotics can be effective for managing these behaviors when first-line treatments such as a_2-agonists are not beneficial (Kurlan 2014; Shprecher and Kurlan 2009).

Emotion Dysregulation

Challenges with emotion regulation in individuals with ASD may manifest as severe irritability or aggression and may include significant maladaptive behaviors (McClintock *et al.* 2003; Tsakanikos *et al.* 2007), including self-injurious behaviors. Emotion dysregulation is also associated with significant distress for patients and stress for families, perhaps even more than that associated with the core defining features (Fitzpatrick *et al.* 2016; Lecavalier *et al.* 2006). The only FDA-and EMA-approved medications for ASD, risperidone at 0.3-3.5 mg daily and aripiprazole at 5-15 mg daily (see section "FDA-and EMA-Approved Treatments"), are used for improving emotion regulation to reduce severe irritability, aggression, and self-injurious behaviors (LeClerc and Easley 2015. A meta-analysis of the literature indicated that these medications are strongly effective for managing emotion regulation in children and adolescents with ASD (Fung *et al.* 2016), even more so than first-generation antipsychotics, which are not frequently prescribed because they are associated with more severe adverse effects, including EPS (Peluso *et al.* 2012). Risperidone and aripiprazole also appear to be superior--in terms of both efficacy and safety (Fung *et al.* 2016)--to the other antipsychotic agents that have been tested, including quetiapine, ziprasidone, and lurasidone (Fallah *et al.* 2019), which showed only minimal to marginal benefits in children and adolescents with ASD.

While antipsychotics have received most of the attention regarding emotion dysregulation in ASD, there is some limited evidence supporting the use of alternative medications. For instance, *N*-acetylcysteine (NAC), an over-the-counter dietary supplement that modulates glutamatergic signaling and increases antioxidative potential in the brain, exhibited moderate effects for reducing the severity of both irritability and stereotyped behaviors in a pilot trial of children with ASD (Hardan *et al.* 2012). NAC also further decreased irritability when used as an adjuvant to risperidone treatment (Ghanizadeh and Moghimi-Sarani 2013; Nikoo *et al.* 2015). Additional agents that exhibited some potential benefit in targeting emotion regulation in trials of autistic patients include atomoxetine (an SNRI), tianeptine (an opioid receptor

agonist), naltrexone (an opioid receptor antagonist), clonidine (an a_2-adrenergic agonist), methylphenidate (a dopamine and norepinephrine reuptake inhibitor), and valproate (an anticonvulsant that blocks some excitatory and increases some inhibitory effects). However, benefits shown by these other agents have been limited, have not yet been replicated, or have been inconsistent across the small-scale studies that have been completed to date. Aripiprazole and risperidone are the current first-line medications for reducing the severity of emotion dysregulation, irritability, aggression, and self-injurious behaviors in children and adolescents with ASD. These medications should be prescribed only for patients who have not responded to psychosocial interventions (e.g., applied behavior analysis-based treatments). Patients taking aripiprazole or risperidone will require regular monitoring for changes in weight, the development of EPS, and fluctuations in serum laboratory results.

Seizures and Epilepsy

The prevalence of seizure disorders in ASD is estimated to be very high, with some reports suggesting that approximately 10% of children and as many as 20%-40% of adolescents and adults with ASD have epilepsy (Amiet *et al.* 2008; Danielsson *et al.* 2005; Liu *et al.* 2022; Viscidi *et al.* 2013). These figures are notably higher than the 1%-2% prevalence observed in the general population (Frye *et al.* 2013). Seizures may also have an earlier onset in some children with ASD, be more resistant to treatment, and appear more frequently in autistic girls and individuals with intellectual developmental disorder, lower language skills, poorer adaptive functioning, or more severe core symptoms (Sansa *et al.* 2011). To date, there have been no RCTs of antiepileptics that specifically focused on epilepsy or seizures in autistic individuals. Currently, the treatment of these conditions in the context of ASD remains the same as in patients without ASD and is largely dependent on the type of seizure that the patient is experiencing. It has been suggested that patients who have epilepsy should first be given a trial on a broad-spectrum antiepileptic (Abou-Khalil 2008); however, no formal recommendations can be made, and treatment recommendations cannot be further refined for individuals with comorbid diagnoses of ASD and epilepsy because of the limitations of the current research.

Sleep Disturbances

Sleep disturbances are also very common in children with ASD, of whom as many as 80% have parent-reported sleep problems (Couturier *et al.* 2005; Polimeni *et al.* 2005). Imbalances in various neurotransmitter systems including melatonin, serotonin, and GABA have been hypothesized to underlie some sleep problems (Kotagal and Broomall 2012; Souders *et al.* 2017), with melatonin being the most commonly prescribed medication for sleep in patients with ASD (Relia and Ekambaram 2018). Most initial small RCTs of melatonin reported benefits for reducing time to sleep onset and increasing sleep duration compared with placebo (Garstang and Wallis 2006; Rossignol and Frye 2011; Wright *et al.* 2011), and a larger RCT ($N = 134$) corroborated these improvements and reported further benefits for reducing bedtime resistance and frequency of nighttime awakenings (Cortesi *et al.* 2012). When melatonin was taken in conjunction with cognitive-behavioral therapy, patients were noted to have even greater improvements in sleep continuity and efficiency. In children 2 years and older, melatonin should be started at 1 mg before bedtime ("Melatonin" 2021) and increased as tolerated. The dosage may be titrated up but should not exceed 10 mg/day. There are also several other alternative medications, such as clonidine, that have been studied in the context of sleep improvement in ASD (Huffman *et al.* 2011), but these medications have limited evidence of efficacy because of the small sample sizes that have been investigated to date (Ming *et al.* 2008; Rossi *et al.* 1999). Atypical antipsychotics including risperidone and olanzapine have also been used for sleep disturbances in some children, but these medications are not first line and are typically prescribed off label (Relia and Ekambaram 2018). The various metabolic and EPS associated with atypical antipsychotics further limit their use to refractory cases only.

Nutritional Deficiencies

Nutritional deficiencies, which are more common in children with ASD than in the general population, are largely associated with food aversions and sensory sensitivities, but there are inconsistent observations about the types and effects of these deficiencies. Despite individuals with ASD eating more restricted varieties of food (Ranjan and Nasser 2015), several investigations have reported no differences in calorie, carbohydrate, or fat intake (Emond *et al.* 2010; Lockner *et al.* 2008; Zimmer *et al.* 2012), and the findings on protein intake are inconsistent (Ranjan and Nasser 2015; Xia *et al.* 2010; Zimmer *et al.* 2012). Children with ASD are also commonly deficient in minerals such as calcium (Hyman *et al.* 2012; Lockner *et al.* 2008; Zimmer *et al.* 2012), iron (Cornish 2002; Herndon *et al.* 2009), and zinc (Cornish 2002; Hyman *et al.* 2012). Common vitamin deficiencies associated with ASD include vitamins A (Cornish 2002; Lockner *et al.* 2008), B_2 (Cornish 2002), B_9 (Al-Farsi *et al.* 2013; Xia *et al.* 2010), B_{12} (Al-Farsi *et al.* 2013; Cornish 2002), C (Evans *et al.* 2012; Xia *et al.* 2010), D (Bandini *et al.* 2010; Herndon *et al.* 2009), and E (Herndon *et al.* 2009; Lockner *et al.* 2008), which are also reflected in serum analysis (Ranjan and Nasser 2015). Although such deficits are common, correction of nutritional deficiencies is not typically associated with any changes in the core symptom domains, and there is not yet convincing evidence supporting nutritional therapy for most patients with ASD (Karhu *et al.* 2020). This absence of evidence also extends to omega-3 supplements, digestive enzymes, and most vitamin supplements (Sathe *et al.* 2017). In cases of severe or symptomatic nutritional deficiency, supplemental nutritional therapy is still warranted and should be considered by the clinical care team. It is important to consider that certain alternative nutritional therapies, such as gluten-free or casein-free diets, are commonly implemented for children with ASD, such that as many as 20% may have been tried on a gluten-free diet (Rubenstein *et al.* 2018). The evidence supporting such dietary approaches is very limited, and dietary restrictions could predispose some patients to deficiencies in essential vitamins, minerals, fiber, and carbohydrates (Mari-Bauset *et al.* 2014; Sathe *et al.* 2017). Thus, it is essential to provide adequate counseling on the benefits and risks of nutritional therapies to support shared decision-making with patients and their caregivers (Hebert 2014).

Novel Pharmacological Agents for the Core Symptoms of Autism Spectrum Disorder

Neuropeptides

Neuropeptides are small proteins (i.e., nanopeptides) that act primarily though G protein-coupled receptors to modulate synaptic transmission. Oxytocin and vasopressin are two such neuropeptides that regulate many important social behaviors in the mammalian brain, including reproduction, childbirth, and social bonding. Administration of oxytocin and vasopressin to humans has been associated with improved social communication, emotion recognition, eye contact, and other prosocial behaviors as well as changes in repetitive and compulsive behaviors (Meyer-Lindenberg *et al.* 2011). Therefore, it should come as no surprise that these particular neuropeptides have received considerable interest for targeting the core symptoms of ASD (Bartz and Hollander 2008), particularly oxytocin. Despite reports that single-dose and open-label intranasal administrations improved social cognition in neurotypical individuals (Guastella and MacLeod 2012) and reduced core symptom severity in individuals with ASD (Guastella and Hickie 2016), RCTs have been inconsistent, with some trials failing to replicate these initial findings (Anagnostou *et al.* 2012; Guastella *et al.* 2015; Yamasue *et al.* 2020). As with other investigational agents, the extreme neurobiological variability across autistic individuals, and individual differences in the neurobiology of the oxytocin system, probably contributed to some differences in treatment response (Kosaka *et al.* 2016; Parker *et al.* 2017; Yatawara *et al.* 2016). Consistent with this observation, a small RCT (N = 32) reported greater improvement in social abilities after 4 weeks of oxytocin compared with placebo, but only after controlling for baseline oxytocin levels, which also predicted treatment response (Parker *et al.* 2017). Unfortunately, a large multisite trial examining the safety and efficacy of oxytocin failed to replicate these preliminary findings on their primary outcome of reciprocal social behaviors (Sikich *et al.* 2021), and there is no strong evidence that supports oxytocin treatment for children and adolescents with ASD.

While investigations of oxytocin have reported disappointing results so far, interest in vasopressin and its role in modulating social abilities has also emerged, with recent studies examining the safety and efficacy of both vasopressin agonists and antagonists. In a double-blind, randomized, placebo-controlled study, daily intranasal administration of a vasopressin agonist treatment was examined in 30 children with ASD for 4 weeks. Compared with placebo, vasopressin was associated with greater improvement in social abilities and decreases in anxiety symptoms and repetitive behaviors (Parker *et al.* 2019). There is also limited evidence supporting the potential for vasopressin antagonists to target some core ASD symptoms. An initial investigation of the vasopressin V1a receptor antagonist balovaptan in adult men with ASD observed changes in secondary endpoints on the Vineland Adaptive Behavior Scale composite score, with some changes in socialization and communication (Bolognani *et al.* 2019), but follow-up studies failed to replicate these findings on the Vineland Adaptive Behavior Scale when it was used as the primary outcome measure (Hollander *et al.* 2022). Because of their potential to directly target the mechanisms that may underlie some of the core social symptoms of ASD, drugs that modulate both the oxytocin (NCT02985749, NCT03466671) and the vasopressin pathways (NCT03204786) are currently being tested in Phase II and III RCTs enrolling children and adults with ASD, including an RCT examining intranasal oxytocin in combination with psychosocial therapies (NCT02918864).

Neurosteroids

Neurosteroids and neuroactive steroids are endogenous molecules that are synthesized either directly from cholesterol in the central nervous system or from peripheral steroid precursors (Baulieu and Robel 1990; Paul and Purdy 1992). They are highly lipophilic and can modulate neuronal excitability in the brain via interactions with ligand-gated ion channels (e.g., GABA_A and *N*-methyl-D-aspartate receptors), alter gene expression through nuclear hormone receptors, and potentially play a critical role in the pathophysiology of some psychiatric disorders, especially neurodevelopmental disorders like ASD in which there are sex differences in the prevalence and clinical phenotype. Pregnenolone is of particular importance because it is the precursor to virtually all neurosteroids. Preliminary investigations have reported that salivary levels of pregnenolone may be elevated in some children with ASD (Majewska *et al.* 2014), whereas plasma levels of pregnenolone sulfate, a primary metabolite, may be reduced (Jansakova *et al.* 2020). Although the potential role of neurosteroids in the pathophysiology of ASD is not yet known, recent pilot studies have reported some promising preclinical and clinical results. Administration of ganaxolone, a synthetic analog of allopregnanolone, to a mouse model of ASD was associated with improved social and reduced repetitive behaviors (Kazdoba *et al.* 2016). The first open-label study of oral pregnenolone in adults with ASD also reported reduced irritability, lethargy, and sensory processing difficulties (Fung *et al.* 2014). The first RCT in adolescents with ASD also reported decreased irritability, stereotypy, and hyperactivity compared with placebo when used as an add-on to risperidone (Ayatollahi *et al.* 2020). There is currently only one active Phase II RCT of pregnenolone in adolescents and adults with ASD (NCT02627508), which will examine changes in irritability as the primary outcome measure.

Pregnenolone is also a negative allosteric modulator of the cannabinoid 1 (CB_1) receptor, which may mediate some of its effects on autism-related symptoms.

Cannabinoids

The endocannabinoid system has also been implicated in ASD, with reports from preclinical models suggesting that it is involved in the modulation of many of the cellular functions and molecular pathways that have been implicated in the disorder, including imbalanced excitation or inhibition, increased oxidative stress, mitochondrial dysfunction, and immune dysregulation (Zamberletti *et al.* 2017). Clinical studies support these preclinical models with reports of lower plasma (Karhson *et al.* 2018) and serum (Aran *et al.* 2019) levels of endocannabinoids in autistic children and adults. Furthermore, preclinical and clinical studies also suggest that agents targeting the endocannabinoid system may provide clinical benefits for patients with ASD. However, investigations into the potential use of medicinal cannabinoids (e.g., cannabidiol [CBD], cannabidivarin) for psychiatric disorders have been limited because of the effects of ethical and societal debates on local and federal regulations, especially regarding their use by children and adolescents. The first clinical trial of an orally administered cannabinoid to children, adolescents, and adults with ASD was only recently completed in Israel. The study authors reported that high-dose CBD and low-dose tetrahydrocannabinol (the main psychoactive compound) were generally well tolerated, with only mild adverse effects, such as somnolence and decreased appetite, but they did not find any treatment-related changes in the primary outcome measure of disruptive behaviors (Aran *et al.* 2021), which may have been related to the heterogeneous sample that was evaluated. Alternatively, they did report significant clinician-rated changes in externalizing behaviors as well as some secondary effects

on social communication. More recently, changes in local regulations and federal enforcement across the United States have allowed new research into the use of medicinal cannabinoids, and at least four clinical trials are being conducted to examine the safety, tolerability, and potential efficacy of various cannabinoid solutions for children and adolescents with ASD. One exploratory open-label study (NCT03900923) and three separate RCTs (NCT04517799, NCT04745026, and NCT04745026) are exploring whether CBD can be used to improve a wide range of core and comorbid symptoms. Thus, further guidance on the use medicinal cannabinoids for children with ASD should be available in the near future.

Beta-Adrenergic Antagonists

b-Adrenergic antagonists (a.k.a. beta-blockers) block the effects of epinephrine and norepinephrine in organs such as the heart and brain and are most commonly used for the treatment of cardiovascular diseases (e.g., hypertension, cardiac arrhythmia, myocardial infarction, and congestive heart failure), glaucoma, and migraine prophylaxis. In psychiatric disorders, b-blockers are commonly used off label in the management of aggression and anxiety, especially performance anxiety (Newman *et al.* 2013), and have received considerable attention in ASD for their potential to target core social symptoms and self-injurious behaviors (Sagar-Ouriaghli *et al.* 2018). Initial case studies indicated that high dosages of propranolol (> 300 mg/day on average; range 120-900 mg/day) may help with management of self-injurious, aggressive, and other challenging behaviors (London *et al.* 2020; Sagar-Ouriaghli *et al.* 2018), but no RCTs of propranolol have been completed to date that support this indication for patients with ASD. Propranolol has received increased attention because of several single-dose challenge studies in adolescents and adults with ASD that reported benefits in cognitive performance, including language processing, working memory (Beversdorf *et al.* 2011; Bodner *et al.* 2012), and social communication (Zamzow *et al.* 2016), that are associated with neurophysiological changes in the brain (Hegarty *et al.* 2017, 2019, 2020b; Narayanan *et al.* 2010). To date, there have been no published results from RCTs of propranolol used for targeting the core symptoms of ASD, but two are under way. These studies will examine target engagement of propranolol in the brain and will assess its efficacy for improving social communication in children with ASD (NCT02871349) and its potential efficacy for targeting irritability, aggression, and self-injurious behaviors in adolescents and adults with ASD (NCT04047355).

Drugs for Neurodegenerative Disorders

Memantine is an *N*-methyl-D-aspartate receptor antagonist that is commonly used to treat Alzheimer's disease, especially when acetylcholinesterase inhibitors are ineffective or contraindicated. Memantine can reduce the potential for excitotoxicity by inhibiting prolonged influx of calcium into the neuron while still allowing neurotransmission because of its low affinity and uncompetitive nature compared with glutamate. Based on this potential to reduce the adverse effects of excessive excitatory signaling in the brain, memantine has received some attention for the treatment of ASD. Early open-label investigations reported some improvements in core areas of social communication and self-stimulatory behaviors (Chez *et al.* 2007) as well as potential improvements in other domains such as memory, irritability, and hyperactivity (Owley *et al.* 2006). Much like other drug trials, results from the first RCTs of memantine for ASD also failed to replicate these early findings, with reports of no drug-related differences on the Social Responsiveness Scale (SRS [Constantino and Gruber 2005]), a questionnaire designed to identify the presence and severity of impairments in social communication in ASD (Aman *et al.* 2017). Subsequent trials then attempted to identify potential responders in an open-label trial before randomization in an RCT (Hardan *et al.* 2019). In the open-label study, 60% of the intention-to-treat sample of children with ASD (*N* = 868) were identified as responders because they exhibited at least a 10-point reduction in the SRS total raw score from baseline. Then 93% of these responders were enrolled in the randomized withdrawal trial, with 33% assigned to placebo, 33% to the full memantine dosage from the open-label study, and 34% to a reduced dosage ([?] 50% of the open-label dosage). Of those randomly assigned, 30% completed the study and approximately 66% discontinued due to loss of their therapeutic response (i.e., [?] 10-point increase in the SRS score from baseline). An approximately equal proportion of participants from each arm relapsed, and there were only negligible differences in terms of treatment response at the end of the trial (Hardan *et al.* 2019). At this time, the available evidence does not support the use of memantine for core symptoms of ASD, and there is only one current RCT that is targeting social deficits in children and adolescents with social impairments (NCT03553875), including ASD.

Nutritional Supplements

Children with ASD often have limited diets because of their selective eating patterns or alternative therapies that may be associated with nutritional deficiencies. Therefore, nutritional supplements are attractive treatment options because they are easily available over the counter, typically well tolerated with minimal side effects, and inexpensive compared with other forms of treatment. The most common supplements that have been investigated to date include vitamins A, C, B_6 and B_{12}, magnesium, and folate, but the available research indicates limited efficacy of these supplements for improving the core symptoms of ASD (Karhu *et al.* 2020). There are some novel applications of other readily available compounds that have exhibited potential efficacy in preliminary trials for ASD. For instance, NAC is a synthetic derivative of the endogenous amino acid L-cysteine that replenishes endogenous levels of glutathione, a primary antioxidant and glutamatergic modulator in the human body. NAC has received considerable attention in psychiatry for targeting a range of symptoms in multiple disorders (Deepmala *et al.* 2015), including ASD. At high dosages, NAC has exhibited some efficacy for treating irritability in autistic children as well as promising preliminary results for reducing the severity of some RRB symptoms (Hardan *et al.* 2012). A single-dose challenge study to examine target engagement of high dosages of NAC in the brains of children with ASD (NCT04278898) and an RCT to assess the potential efficacy of NAC for reducing core RRB severity (NCT05664789) are currently being conducted.

Another promising nutritional supplement for children with ASD is sulforaphane. Sulforaphane is an organosulfur compound that is derived from broccoli sprouts and like NAC has both antioxidative and anti-inflammatory effects in the central nervous system. In the first preliminary trial, sulforaphane reduced some aberrant behaviors, such as irritability and hyperactivity, as well as the severity of social impairments in adolescents and adults with ASD (Singh *et al.* 2014). However, these results were only

partially replicated in a subsequent pediatric study, such that changes in core social symptoms did not differ from those of patients taking placebo (Zimmerman *et al.* 2021). There is currently one other RCT under way to further investigate sulforaphane as a potential treatment for core ASD symptoms (NCT02677051).

Finally, several recent studies have also examined the potential for folinic acid to target language delay and improve communication skills in children with ASD. Preliminary findings from pilot RCTs of folinic acid derivatives (i.e., leucovorin) included improved language and communication scores (Frye *et al.* 2018; Renard *et al.* 2020) as well as reduced inappropriate speech and problem behaviors when used as an adjuvant treatment to risperidone (Batebi *et al.* 2021). These promising findings have facilitated the development of several larger RCTs that are currently examining the potential efficacy of folinic acid in children with ASD between the ages of 2.5 and 12 years who have language delay (NCT04060030, NCT04060017, NCT02839915).

Summary of Recommendations and Guidance

The optimal approach for treating autistic patients who are seeking mental health care services is to maintain a balance between psychosocial/behavioral interventions and medications. It is critical to reevaluate treatment regimens on a regular basis to determine whether specific medications or psychotherapies continue to be beneficial. This strategy will avoid excessive polypharmacy and eliminate therapies that are not benefiting the patient. In light of the limited evidence supporting the efficacy of available pharmacological agents in the treatment of core features of ASD, the focus of the psychiatric evaluation is to identify the existence of any DSM-5 diagnoses. This approach will allow the use of specific interventions to treat specific comorbid disorders. For example, making the diagnosis of major depressive disorder could support prescription of an antidepressant. However, the complex and atypical presentations of psychiatric symptoms in people with ASD, especially those with intellectual developmental disorders, make pinpointing particular comorbid disorders difficult or impossible. Therefore, targeting symptoms such as aggression and irritability with medications may be the only alternative approach, even though is not ideal. It may also be tempting to consider targeting different behaviors with more than one medication. For example, children with ASD commonly present with sleep disturbances, anxiety symptoms, and inattention, hyperactivity, and impulsivity. This constellation of symptoms probably requires different medications, but it is recommended that target symptoms be prioritized on the basis of either severity or patients' and parents' preferences to minimize the potential for more complex and severe adverse events, which may be more common in autistic patients.

By definition, individuals with ASD have difficulties with their expressive abilities, and this limitation may be even more pronounced in those with intellectual developmental disorders. Hence, assessing emergent side effects and monitoring treatment progress can be very challenging, and the clinician should request input from multiple sources in addition to the patient. Reporting on dry mouth or cognitive side effects, for instance, might not be possible for some patients. In these cases, behavioral dysregulation might be the manifestation of some adverse effects related to the prescribed medications. Determining whether benefits are being observed is also not straightforward at times, and it is often necessary to gather information from all involved parties, including parents or legal guardians, teachers, classroom aides, bus drivers, in-home therapists, group home staff, and day program supervisors. The collection of standardized measures and questionnaires is also critical to support a more comprehensive evaluation of the overall behaviors and symptom profiles and, more importantly, to allow a comparison over time and across settings and contexts. Multiple scales are available to help measure different symptom domains, and some of the most commonly used instruments are outlined in the appendix table.

Finally, once a medication is initiated, response rates can vary such that some individuals may respond dramatically, while others exhibit only a minimal response. This variability is not surprising considering the extreme neurobiological heterogeneity of ASD and involvement of many different neural networks and neurotransmitter systems. Therefore, rechallenging with the same medication 1 or 2 years later might lead to a different response or better tolerance because the targeted brain pathways are developing over time. The sensitivity of a neural network to one medication or lack of responsiveness to another might also change as the brain is maturing. For example, it is not surprising if a 7-year-old girl with ASD and ADHD is not able to tolerate 10 mg/day of methylphenidate, with emergent irritability and sleep disturbances, but is able to take a 20 mg/day extended-release formulation of the same compound at age 10 years with good response.

Future Directions and Advancement of Precision Medicine

Current Limitations

Behavioral therapy is typically the first-line treatment for patients with ASD, and pharmacological interventions are currently directed at the management of comorbid psychiatric and medical conditions. The lack of pharmacological interventions for the core symptoms of ASD is partially due to limitations of drug trials for this patient population. First and foremost, treatment response to even the most efficacious drug intervention is extremely variable across patients. The extreme phenotypic and neurobiological heterogeneity across ASD patients, changes in treatment response over different developmental periods, increased incidence of psychiatric and medical comorbidities, and limitations of the available outcome measures for assessing treatment-related changes have all hindered clinical trials for ASD to date. Innovative clinical trial designs will be necessary to account for and address these complicating and confounding factors and will be critical for advancing the development of new pharmacological treatments for patients with ASD who are seeking mental health care services.

Domain-Specific and Objective Outcome Measures

One of the most important aspects of clinical trial design is the selection of reliable and valid outcome measures that are sensitive to change. Outcome assessment tools used to measure changes in core ASD symptom severity have been extremely variable across clinical trials, as have their psychometric properties. Attempts have been made to identify the most appropriate outcome measures for trials targeting SCI and RRB (Anagnostou *et al.* 2015; Scahill *et al.* 2014), but there continue to be significant limitations in even the most frequently recommended approaches. The appendix table at the end of this chapter presents examples of traditional instruments that are commonly used for monitoring core symptom severity in autistic patients, including the SRS, 2nd Edition, for SCI (Constantino and Gruber 2012), the Restricted Behavior Scale for RRB (Lam and Aman 2007), and the Short Sensory Profile for sensory processing patterns (Tomchek and Dunn 2007). Recent investigations using big data applications for psychometric research in ASD have also begun to address some of the limitations of these previous measures by developing novel assessment tools for specific subdomains of the core symptom domains, such as the Stanford Social Dimensions Scale (Phillips *et al.* 2019) and the Dimensional Assessment of Repetitive Behaviors (Uljarevic *et al.* 2023).

Combination of Pharmacological and Psychosocial Interventions

Psychosocial and behaviorally based interventions are the first-line treatment for children with ASD, whether they are targeting core features or comorbid domains. However, much like with pharmacotherapies, treatment response to psychosocial and behavioral interventions is also extremely variable across autistic patients. Some of this variability in treatment response is probably related to individual differences in cognition and behavior, such as attention, emotion regulation, and externalizing or internalizing behaviors (Lerner *et al.* 2012). Thus, pharmacological agents that can improve one symptom domain in children and adolescents with ASD may also help optimize treatment response to behavioral or psychosocial interventions targeting other symptom domains. For instance, antipsychotic medications are associated with a faster response to intensive behavioral interventions targeting aggression (Frazier *et al.* 2010) and improving adaptive and social communication skills when used in combination with parent training to reduce maladaptive behaviors (Scahill *et al.* 2012). More importantly, RCTs are starting to assess the efficacy of combined pharmacological and psychosocial treatments, which may help optimize patient outcomes and advance the development of precision medicine for subgroups within the autism spectrum.

Biomarkers

Finally, there is mounting evidence that there are clinical and biological subgroups within the autism spectrum, for which optimal treatment approaches probably differ from mainstream recommendations. Clinical or phenotypic subgroups are those who share similar cognitive and behavioral symptom profiles. For instance, autistic individuals with significant cognitive challenges (e.g., IQ < 70), delayed language development with minimal spoken communication skills (e.g., nonverbal), high severity of certain types of RRB (e.g., specific rigidities), or high versus low motivation for social engagement and interaction may have more in common with each other than with the general ASD population and be more likely to respond to the same interventions. Similarly, biological and genetic subgroups who share similar neurobiological profiles may also be more likely to respond to certain interventions. For instance, autistic individuals with shared genetic architectures (e.g., fragile X), brain abnormalities (e.g., macrocephaly or cerebellar alterations), neurotransmitter imbalances (e.g., hyperserotonergia or excitation/inhibition imbalances), or neurophysiological alterations (e.g., seizures) may be more likely to respond to some treatments than to others. Genetics and more specifically pharmacogenomics, which examines the role of the genome in drug response, may also potentially aid in identifying subgroups within ASD. Biomedical scientists have begun to make progress in other areas of medicine (e.g., oncology), and there is great promise for psychiatry in general as well as for the field of ASD specifically. Although limited work focused on pharmacogenomics in ASD has been published, the available literature supports testing for two cytochrome P450 genes (*CYP2D6*, *CYP2C19*) before prescribing certain antidepressants and antipsychotics, testing for human leukocyte antigen genes (*HLA-A* and *HLA-B*) before using certain mood stabilizers, and screening for genes affecting the urea cycle (*OTC*, *CSP1*) before considering valproate when a urea cycle disorder is suspected (Bousman *et al.* 2021).

Conclusion

Despite the promising research described above, no clear progress has been made in developing new interventions for the core symptom domains of ASD and other developmental disorders or in identifying specific subgroups with distinct neurobiological underpinnings or common clinical features, including prognostic outcomes. Therefore, additional research is critical and must include the development of innovative and adaptive study designs, more sensitive assessment and measurement tools that incorporate big data science and artificial intelligence, and new patient stratification and surrogate outcome markers to advance clinical research for ASD. This innovative research will also aid in the identification of novel therapeutic agents for targeting specific core symptom domains such as insistence on sameness and low social motivation, as well as comorbid domains such as anxiety and depression. Ultimately, more objective assessment tools and the identification and study of subgroups within the autism spectrum should help reduce trial and error of interventions and should advance precision medicine for autistic patients who are seeking mental health care services.

APPENDIX

Outcome Measures for Assessment of Core Symptom Domains in Autism Spectrum Disorder

APPENDIX: Details of outcome measures used for clinical monitoring and clinical trials for autism spectrum disorder

Domain/scale or measure	Reporter	Age range	Administration time (min)	No. items	Subscales

Acknowledgment. The authors would like to thank Katherine Paszek (Stanford University) for creating this table.

Domain/scale or measure	Reporter	Age range	Administration time (min)	No. items	Subscales
Global functioning					
Clinical Global Impression (CGI) (Busner and Targum 2007) * Clinician-administered summary interview that takes into account all available information, including a knowledge of the patient's history, psychosocial circumstances, symptoms, behavior, and the impact of the symptoms on the patient's ability to function.	Clinician	Any age	Varies with familiarity with patient	12	Severity of illness Global improvement Efficacy index
Social communication					
Social Responsiveness Scale, 2nd Edition (SRS-2) (Constantino and Gruber 2012) * Questionnaire that assesses the presence and severity of social impairments related to ASD. Can help distinguish between social impairment in ASD and social impairment that occurs in other disorders; can also be used to monitor symptoms across the life span.	Caregiver, Teacher, Self-report	Preschool (2.5-4.5 years), school age (4-18 years), adult (19+ years)	15-20	65	Social awareness Social motivation Social communication Social cognition Restricted, repetitive behaviors and interests
Social Communication Questionnaire (SCQ) (Rutter *et al.* 2003) * Questionnaire (lifetime & current forms) that assists with evaluation of communication skills	Caregiver	4+ years	< 10	40	Reciprocal social interaction Communication Repetitive behavior

Acknowledgment. The authors would like to thank Katherine Paszek (Stanford University) for creating this table.

Domain/scale or measure	Reporter	Age range	Administration time (min)	No. items	Subscales
and social functioning in children who may or may not have ASD. Often used as a screener for ASD and requires caregivers to be familiar with the developmental history and current behavior of the individual.					
Stanford Social Dimensions Scale (SSDS) (Phillips *et al.* 2019) * Dimensional, quantitative parent-report questionnaire designed to capture key social processes and skills that, if impaired, can impede a person's ability to navigate the complexities of the social worlds. Can be used in both normative and clinical populations.	Caregiver	Any age	15-20	58-71	Social motivation Social affiliation Expressive social communication Social recognition Unusual approach
Brief Observation of Social Communication Change (BOSCC) (Grzadzinski *et al.* 2016) * Videotaped observation assessment of social communication behaviors in children with ASD. Sensitive to changes in social communication behavior and can be administered by minimally trained examiners and coded	Clinician	1-5 years	12	15	Social communication Restricted, repetitive behaviors

CHAPTER 67

Treatment of Psychiatric Emergencies

Roger L. McRoberts, M.D.
Steven J. Garlow, M.D., Ph.D.

Psychiatric emergencies occur in every situation and in every setting, and the diagnosis and management of these emergencies is a fundamental skill of every practicing psychiatrist. Although often managed in specialized crisis stabilization units, psychiatric emergencies occur in other locations, such as general medical/surgical units, outpatient clinics, general emergency departments (EDs), and other, nonclinical areas. The effective practice of emergency psychiatry requires a broad range of knowledge and clinical skills, including general and consultative psychiatry, behavioral neurology, psychopharmacology, individual and family psychotherapy, geriatric psychiatry, and addiction medicine. In addition, a basic knowledge of forensic and legal issues is essential in all settings.

The increasing prevalence of psychiatric emergencies as reflected in general hospital ED visits is striking. There were 420,000 ED visits per year for attempted suicide and self-injurious behaviors between 1993 and 2008 (Larkin *et al.* 2005). Between 2007 and 2016, ED visits related to mental health complaints rose from 6.6% to 10.9% (Theriault *et al.* 2020). This trend of steady increases in psychiatric emergency presentations to general hospital EDs has continued, despite the ongoing impact of COVID-19 (Holland *et al.* 2021).

Patients with emergent behavioral and psychiatric syndromes are often unable or unwilling to provide accurate historical details; therefore, the clinician must rely on collateral sources of information, including friends, family, and previous treatment providers. One consequence of this process of data collection is that absolute patient confidentiality, the standard of care in other clinical settings, is more tenuous. The Health Insurance Portability and Accountability Act (HIPAA) regulates all disclosures of protected health information (PHI) by health care providers. In 2014, the U.S. Department of Health and Human Services issued guidance on the implementation of HIPAA in the setting of psychiatric emergencies (U.S. Department of Health and Human Services 2014). In the context of a psychiatric emergency, the need to acquire critical information supersedes the individual's absolute right to privacy. The guiding principle is the determination of the clinician, based on professional judgment, that disclosure of certain PHI would be in the best interests of the patient in that emergent situation. Disclosures to family, friends, and other care providers can be made if the patient does not object when informed of the proposed disclosure, or if, in the professional judgment of the clinician, the patient does not have capacity based on their mental status (examples being psychosis, substance intoxication, or unresponsive states). In emergent situations, resources such as medical records, friends, and relatives may provide critical data for diagnosis and treatment. There is no prohibition in HIPAA against a clinician listening to information provided by family, friends, and other care providers or reading outside clinical records. In the emergency situation, accurate diagnosis and treatment is critical, and although any health disclosures should be minimized, the focus is on safety. There are other circumstances in which there is a mandated breach of confidentiality, including situations in which a patient is at risk of harming self or others (e.g., knowledge of potential child or elder abuse). HIPAA does not prevent these mandatory disclosures to protect the safety of the patient or others. Specific disclosure and third-party contact requirements vary by jurisdiction and should be reviewed by psychiatrists who are subject to them.

As the numbers of psychiatric emergency cases continue to increase, and both a shortage of psychiatrists and increasing safety concerns during a pandemic impact delivery, telemedicine has become increasingly important in the practice of emergency psychiatry. Telepsychiatry was described in the literature in 1973 (Dwyer 1973) and primarily existed to provide care in urgent cases to remote areas. Telepsychiatry use has peaked during the COVID pandemic, increasing from less than 1% of visits to (in places heavily impacted by COVID) up to 80% of visits (FAIR Health 2020). Telemedicine has become increasingly utilized by specialty services, including emergency psychiatry (Reinhardt *et al.* 2019). Providers who engage in telepsychiatry must be aware of regional, state, national, and board level regulations that surround telepsychiatry, including but not limited to information security, insurance restrictions, and prescribing concerns.

Telepsychiatry is best utilized when it includes voice (or ideally voice and video), as this is seemingly superior to text-only exchanges (Galea *et al.* 2020). When the emergency permits, it is critical to acquire and document the patient's consent for the use of a telemedical device. Because there will always be potential connectivity or technical issues on either end of the remote visit, ideally the provider should test connectivity and video quality before the emergency presents itself. Given the potential for disruption, a provider should spend as much time as possible reviewing relevant documentation and laboratory findings before the visit is initiated. Although the nature of the emergency may preclude this, ideally patients should be asked directly if they feel comfortable with the process or if there are any off-screen issues that would prevent them from maintaining confidentiality of their health information. Providers should work to develop and maintain a therapeutic alliance, which is more challenging in remote interactions (Flint and Kotwal 2020). Performing a full neurological or physical exam is difficult (Benziger *et al.* 2021) but possible to approximate, and providers will need to work to gather as much collateral information as possible from available staff and families.

Clearly, development of a well-trained workforce of clinicians to deal with this rising tide of psychiatric emergencies is an urgent national imperative. The Accreditation Council for Graduate Medical Education (ACGME) does specify training requirements for emergency psychiatry for all psychiatric residents, which must be conducted in an organized, supervised psychiatric emergency service. Acknowledging the increasing importance of this education, the ACGME requirements exclude outpatient or on-call experiences from counting toward this experience. Efforts should continue to be made through the American Association of Directors of Psychiatric Residency Training (AADPRT) and other organizations to ensure that all psychiatry residents receive adequate, high-quality training in psychiatric emergencies. But given that in a large proportion of psychiatric emergency cases individuals present to general emergency rooms, it is clear that training in diagnosing and managing psychiatric emergencies should be provided to professionals other than psychiatrists, from physicians in emergency medicine residencies through nurses and other practitioners.

Nonpharmacological Psychiatric Emergencies

Situations that require emergent psychiatric intervention, but not psychopharmacological treatment, include evaluation of need for hospitalization, assessment of suicide or homicide risk, determination of ability to care for self, and requirements to notify third parties in order to ensure the safety of the patient or others (Table 67-1). Emergency psychiatrists must attempt to make predictions about patients' future behavior and work to take appropriate preemptive action to prevent negative outcomes. All states have civil commitment laws that allow for the involuntary hospitalization of persons who by virtue of a mental illness may be considered an imminent risk to themselves or others. Typically, these laws allow for commitments of 48-72 hours in secure receiving facilities. Involuntary hospitalization beyond this holding period for observation and stabilization generally involves judicial review.

TABLE 67-1. Psychiatric emergencies that do not require pharmacological intervention

Emergency	Intervention
Suicidal state	Risk assessment
	Decision to admit
Homicidal state	Evaluation for psychiatric disorder
	Risk assessment
	Decision to admit
	Notification to others if indicated
Child, elder, or spouse abuse	Notification of law enforcement and other agencies
	Referral to safe shelters
Grave disability (inability to care for self)	Medical evaluation
	Attempt to gather collateral information
	Decision to admit

Need for Hospitalization

Decisions to hospitalize a psychiatric patient are dependent on many factors but are always based on the welfare of the patient. There should be clear, definable treatment objectives for hospitalization, and the facility in which the patient is to be admitted should be capable of meeting those needs. Other factors that can contribute to the decision to hospitalize a patient include availability of psychiatric hospital beds and admission authorization by third-party payers (Simon 1998). Thus, the clinician must balance the availability of resources with the needs of individual patients.

Once the decision is made to hospitalize a patient, every effort should be made to have this occur on a voluntary basis. This is the first step in establishing therapeutic rapport with patients. The indiscriminate use of involuntary commitment can set up the perception of an adversarial relationship between patients and treatment providers (Olofsson and Jacobsson 2001). Avoiding experiences that elicit the perception of being "locked up" is one way of facilitating the long-term care engagement of the mentally ill patient.

Suicidal State

Suicide is the twelfth leading cause of death in the United States, with 45,979 suicide deaths in 2020, which translates into a population rate of around 14 deaths per 100,000 per year (Centers for Disease Control and Prevention 2023). The total age-adjusted suicide rate in the United States increased 35.2%, from 10.5 per 100,000 in 1999 to 14.2 per 100,000 in 2018, before slightly declining to 13.9 per 100,000 in 2019, and remained stable in 2020 (National Institute of Mental Health 2021). The increasing rate of suicide is indicative of the lack of impact of any specific psychiatric treatments on the suicide rate. Several studies have failed to find any association between the availability of psychiatric treatment resources and the suicide rate (Garlow *et al.* 2002; Lewis *et al.* 1994).

There is no evidence that predicting suicide can be accomplished with any degree of sensitivity or specificity (Kessler *et al.* 2020), and attempting to do so can provoke significant anxiety in the clinician (Pokorny 1983, 1993). This is relevant because almost half of adults who die by suicide have been seen by a provider within the past month, and almost half have visited an ED within the past year (Ahmedani *et al.* 2014; Luoma *et al.* 2002). Risk of suicide should be viewed in the context of these limitations. The relationship between suicidal ideation, attempted suicide, and completed suicide is complex and inconclusive (Moscicki 1997).

Suicide risk is estimated by assessing both acute and chronic risk factors (Table 67-2), which include patient characteristics, nature of suicidal behavior, availability of a high-lethality means, and level of and access to psychosocial support systems (e.g., family, friends, community) (Hall *et al.* 1999; Simon and Gutheil 2002). Acquiring reliable and accurate past and collateral history is essential. Acute risk factors are most predictive of emergent suicidality and should carry the most weight in the decision to hospitalize a patient (Busch *et al.* 2003).

TABLE 67-2. Common acute and chronic risk factors for suicide

Acute	Chronic
Previous suicide attempts	Gender (male : female = 4:1)
Escalating anxiety/panic attacks	Age (18-24 years; > 65 years)
Access to highly lethal means	American Indian/white
Hopelessness	Sexual minority
Substance intoxication	Access to highly lethal means
Mood-congruent nihilistic delusions	Family history of suicide
Psychic turmoil	History of mental illness
Recent discharge from a psychiatric hospital	Previous suicide attempts
Global insomnia	History of substance use disorders
	Marital status
	Childhood adversity

Generating a comprehensive suicide risk assessment involves organizing and balancing risk with protective factors. Clear documentation of these risk and protective factors, steps taken toward intervention, and associated clinical reasoning is essential. A basic statement describing competency should also be included. In the case of a patient chronically at risk for suicide, clearly documenting this pattern and obtaining a second opinion to corroborate the treatment plan and objectives may be beneficial.

Acute Risk Factors

A history of attempted suicide is the strongest single predictive factor for risk of completed suicide (Bostwick *et al.* 2016). Other acute risk factors include increasing anxiety and frank panic attacks, psychic turmoil, global insomnia, mood-congruent nihilistic delusions, profound hopelessness, and recent discharge from a psychiatric hospital (Busch *et al.* 2003; Deisenhammer *et al.* 2007; Fawcett 1992; Fawcett *et al.* 1990).

Current intoxication is another acute risk factor, as patients with a history of alcohol and drug use have a 10-14 times greater risk of completed suicide (Wilcox *et al.* 2004). Almost all substances of abuse are associated with an increase in the risk of suicide. The suicide hazard ratio is 1.35 for cocaine use, 2.10 for psychostimulant use, 3.83 for benzodiazepine use, 3.89 for cannabis use, and 11.36 for sedative use (Bohnert *et al.* 2017). Recent alcohol consumption plays a role in 25%-50% of all suicides (Cornelius *et al.* 1998).

Previous suicide attempts are known precursors for completed suicide; thus, nonlethal suicide attempts are acute risk factors (Deisenhammer *et al.* 2007; Isometsa and Lonnqvist 1998; Tejedor *et al.* 1999). Consideration should be given to the actual lethality of the attempt; the patient's perception of that lethality; efforts made to conceal the attempt; calls for help; contacts with friends or family during the attempt; and use of a firearm. Access to firearms must always be determined in suicide assessment--in the United States, firearms were used in over half of completed suicides (Centers for Disease Control and Prevention 2023).

Chronic Risk Factors

Males complete suicide three to four times more often than females, but females demonstrate a higher number of suicide attempts. Historically, males tend to choose more lethal and violent means of suicide than females. This may be changing. Among males, firearms remain the most commonly used method of suicide. Firearm-related suicide has increased in females and represented the leading means of completed suicide in 2020 (Centers for Disease Control and Prevention 2023). From 2000 to 2020, male suicide rates were consistently highest in those ages 75 and older. Female suicide rates between ages 45 and 64 were the highest during this time frame.

Rates of suicide are higher for American Indians/Alaska Natives and whites than for any other racial group. These suicide rates for specific racial groups change with the age and gender of the individual. In one study, African American males constituted the largest group, numerically and statistically, of teenage suicide victims but accounted for only 26% of victims from all age groups. In this same dataset, African American females accounted for only 3% of all suicides, with only one occurring in an individual older than 45 years (Garlow *et al.* 2005).

Approximately 90%-95% of suicide victims have a major psychiatric illness, of which approximately half have a mood disorder (Angst *et al.* 2002; Fawcett 1992; Harris and Barraclough 1997). Among individuals with bipolar disorder, males are at higher risk for suicide, especially those at an earlier phase of the illness, those who are currently in a depressed state, and those with comorbid substance abuse (Simpson and Jamison 1999). Patients with alcohol or other substance use disorders have higher rates of completed suicide than the national average, with alcoholic patients having a suicide rate that is twice the national average (Fowler *et al.* 1986). For individuals with alcohol use disorder, comorbid depression and recent interpersonal loss increase risk (Murphy and Wetzel 1990; Murphy *et al.* 1992). A family history of suicide increases suicide risk independent of a family history of mental illness (Qin *et al.* 2002, 2003). Sexual minorities are at an increased risk of suicide (Salway *et al.* 2019), as are adults who experienced childhood abuse (Zatti *et al.* 2017).

Patients with borderline personality disorder often express ongoing suicidal ideation; as a result, suicidality becomes embedded in their sense of self (Soloff *et al.* 1994). This can manifest as repeated acts of self-injurious behavior, such as cutting and sublethal overdoses. These patients can be very difficult to manage and can put a great deal of strain on the emergency medical and mental health delivery system. A consistently applied treatment plan, restrained responses on the part of clinical staff (minimizing countertransference behaviors), and use of secure 24-hour observation areas can be particularly useful in managing these patients. The goal is to allow patients to deescalate so that they can be discharged back into their ongoing outpatient treatment regimens (Maltsberger and Buie 1974).

Protective Factors

When a suicide risk assessment is being formulated, it is critical to note protective factors in addition to the presence or absence of acute and chronic risk factors. Protective factors against suicide include an expression of responsibility toward family, fear of social disapproval, moral objections to suicide, greater coping skills, and greater fear of suicide (Malone *et al.* 2000). Social connectivity also serves a protective role for depressed patients, as first described by Emile Durkheim (1951). Having close familial relationships, being in a stable marital or other partnered relationship, living with another person (family or friend), and having dependent children are all protective factors (Kleiman and Liu 2013). Belonging to certain cultural groups, such as a community of faith, and having moral objections to suicide are associated with lower rates of suicide (Dervic *et al.* 2004, 2006).

Management of Suicidal Patients

Ensuring safety is the first and most important step in managing a potentially suicidal patient. This can best be accomplished through admission to a secure patient observation area. If no such facility is available, close observation by a trained staff member is another option. Staff assigned to monitor patients should be given specific instructions regarding their role and responsibilities.

The decision to hospitalize a potentially suicidal patient should consider both acute and chronic risk factors; specific treatment needs of the patient; availability of any other treatment options, including partial hospitalization, day treatment, and crisis group home settings; and the social support network of the patient. Patients who are intoxicated and expressing suicidal ideation should be allowed to sober up before receiving a more definitive assessment. No-harm contracts between patients and clinicians are not useful in making treatment decisions with suicidal patients (Kroll 2000; Simon 1999). Focusing on the acute behavioral state of the patient (anxiety, agitation, and insomnia), the presence of chronic risk factors, and access to high-lethality means (firearms) is much more relevant to making the decision to hospitalize the patient.

Patients who are not hospitalized require close follow-up, ideally including an identified treatment provider and instructions for the patient and family members on what to do in case of symptom worsening. Recommendations for management of acutely suicidal outpatients have been operationalized into an approach called Safety Planning Intervention (SPI). SPI is specifically designed to be deployed in ED settings for patients with suicidal ideation who are not hospitalized. A trained staff member assists the patient in developing a written document that includes warning signs, coping mechanisms, and sources of support and other treatment resources (Stanley and Brown 2012). Individuals with access to high-lethality means should be advised to remove these items from the home. Firearms and medications lethal in overdose should be neither in the home nor readily accessible. Family members and friends may be consulted to assist with the removal of these items from the patient's possession (Mann *et al.* 2005).

Psychotherapy has shown benefit in the management of suicidal patients, with reduced mortality in patients who engaged with a therapist (Erlangsen *et al.* 2015). In one seminal report on the use of cognitive-behavioral therapy (CBT) with suicidal patients initially assessed in a general ED, patients who received a 10-session CBT intervention were much less likely to make a second suicide attempt within the 18-month follow-up period compared with those who did not receive this intervention (Brown *et al.* 2005). The patients who received CBT also had greater improvements in depression symptom severity and lower levels of hopelessness than those in the control group.

Although management of emergent suicide risk has historically not been considered to warrant acute pharmacological interventions, ongoing trials suggest that the

dissociative anesthetic agent ketamine may have specific therapeutic benefit in suicidal patients (Price and Mathew 2015). Single doses of subanesthetic ketamine (0.5 mg/kg body weight) have been shown to rapidly relieve symptoms of depression and suicidal ideation (Wilkinson *et al.* 2018). The antisuicide response appears to occur regardless of the impact on severity of mood symptoms, suggesting a specific antisuicide action of ketamine (Ballard *et al.* 2014). It remains unclear as of this writing whether ketamine can be useful in the management of unipolar depression or in longer-term treatment. Clearly, additional research is needed to fully determine the utility, if any, of this intervention in general clinical practice.

Homicidal State

Establishment of a psychiatric diagnosis is the first step in developing a management plan for a patient expressing homicidal ideation. Suicide most often occurs in the context of a mental illness, but with regard to homicide and assault, people with severe mental illness are significantly more likely to be the victim of violence than the perpetrator. Psychotic disorders are associated with an increased risk of violence, but this behavior is more closely correlated with substance abuse (Fazel *et al.* 2009).

Expressions of anger, hostility, rage, and violent intent occur in many interpersonal situations and conflicts in which the perpetrator does not have a psychiatric disorder. In these cases, once a determination has been made that the individual is not psychotic or delusional or expressing homicidal ideation due to some other psychiatric disorder, appropriate interventions are in the domain of law enforcement, not psychiatry.

If a patient who is expressing homicidal ideation is not admitted to a psychiatric facility, the clinician must give very careful consideration to the need to notify the intended victim and law enforcement agencies based on the principles set forth in *Tarasoff v. Regents of the University of California* (1976) (Simon 1998; Walcott *et al.* 2001). This case established a precedent for mental health workers to breach confidentiality to notify an intended victim and law enforcement agencies if they are aware of a patient's plan to harm that individual. Adoption of the principles set forth in the *Tarasoff* ruling varies by state but must be considered.

Predicting which individuals may act on homicidal ideation is very difficult (Fazel *et al.* 2009; Resnick and Scott 2000). Factors that contribute to this assessment are the specificity of the plan, identity of the victim, access to high-lethality means (firearms), capacity of the patient to persist in the plan, and proximity of the perpetrator to the intended victim (Borum and Reddy 2001). Even with a careful history, assessment, and appropriate intervention, preventing an adverse outcome may not be possible.

Child, Elder, or Spouse Abuse

Vulnerable individuals--children, elderly persons, or those with developmental disabilities and/or special needs--may present with psychiatric emergencies resulting from abuse and neglect. Responses to abuse and neglect may take the form of behavioral disturbances, self-injurious behavior, or failure to thrive and diminished self-care. The initial response from providers should be a careful and comprehensive evaluation and data gathering. When abuse and/or neglect is suspected or confirmed, involvement of social or legal services is an appropriate step. Depending on the locality and rules defining mandatory reporting by providers, notification of third parties may be required (see section below). Although care requirements in such cases will be determined by the underlying condition of the individual and the consequences of the abuse or neglect, interventions could involve medical treatment, general restorative measures (e.g., nutrition, physical therapy), and/or mobilization of social resources for needs such as housing and other care.

Notification of Third Parties in Cases of Abuse/Neglect or Intent to Harm

The principles set forth by the *Tarasoff* ruling in California encourage clinicians to act in the best interests of the intended victim, with notification of the intended victim and law enforcement agencies in the case of expressed homicidal ideation. This places a unique burden on psychiatrists--to predict future behavior of a patient and to assume responsibility for the welfare of another person with whom the psychiatrist does not have a therapeutic relationship.

Another circumstance that requires breach of patient confidentiality is notification of authorities in cases of suspected child abuse and/or neglect. All states have statutes that require clinicians of all disciplines to notify the appropriate agency in the case of suspected child abuse. Many states also have laws for reporting elder abuse and abuse of other vulnerable individuals. Some states have requirements to report abuse or illness based on profession.

Grave Disability and Inability to Care for Self

Another situation for which involuntary commitment laws exist is when a patient by virtue of a mental illness is unable to care for themselves. The nature of these commitment laws will vary by location; for example, some states also include "as a result of substance abuse disorders" under this heading, whereas others do not (Hall and Appelbaum 2002). It must be considered whether the patient cannot provide adequately for basic needs, shelter, food, and medical attention because of a mental illness. A common example of this situation is a patient with a psychotic disorder who is living on the streets, without regular or adequate nutrition, and neglecting their ongoing medical conditions. This situation is not the same as that in which a person is homeless because of some other occurrence or circumstance, because homelessness does not in itself constitute grave disability. Another common situation that falls under this heading is a patient with dementia or other profound cognitive impairments who has wandered away from their caregivers. In these cases, there is evolving literature surrounding "dispositional capacity" assessments. These evaluations should reflect the patient's ability to understand their circumstances, their ability to care for themselves, and the availability of others who can help meet their needs (Bourgeois *et al.* 2017).

Psychiatric Emergencies Requiring Minimal or Adjunctive Pharmacological Intervention

Psychiatric emergencies requiring minimal or adjunctive pharmacological intervention occur in many different situations, although many share a common thread of developing in response to some discrete, identifiable stressor (Table 67-3). The practice of crisis intervention psychiatry involves identifying the root cause or stressor of the presenting syndrome and developing a focused treatment plan. The principal therapeutic goals are to alleviate short-term distress, rapidly return the patient to their previous level of functioning, and prevent the development of a more serious long-term syndrome. The judicious use of psychopharmacological agents, in concert with psychotherapeutic, psychosocial, and family system interventions, can be particularly effective in these emergencies.

TABLE 67-3. Psychiatric emergencies requiring minimal or adjunctive pharmacological intervention

Emergency	Intervention
Adjustment disorder or acute grief	Diagnostic/psychosocial assessment
	Psychotherapy
	Social and family system interventions
	Short course of sedative-hypnotic
	Short course of benzodiazepine
	Selective serotonin reuptake inhibitor
Rape, assault, or trauma	Medical evaluation and treatment
	Law enforcement notification
	Psychotherapy
	Short course of sedative-hypnotic
	Short course of benzodiazepine
	Insult-specific psychotherapy:

Emergency	Intervention
	Rape counseling
	Spousal abuse counseling
	Violence victim counseling
Borderline personality disorder	Controlled environment/deescalation
	Psychotherapy (e.g., dialectical behavior therapy)
	Low-dosage antipsychotics
Panic disorder	Medical evaluation
	Short course of benzodiazepine
	Outpatient referral

Adjustment Disorders

Adjustment disorders are defined as the development of emotional or behavioral symptoms in response to an identifiable stressor occurring within 3 months of the onset of the stressor (American Psychiatric Association 2013). Common clinical manifestations of adjustment disorders encountered in psychiatric emergency settings involve a mixture of anxiety, depressive, and neurovegetative symptoms in response to some external stressor or crisis. The potential stressors are myriad, including death of a family member or friend, job loss, diagnosis of a serious medical condition, divorce and other disturbances of family function, and financial hardship. The response to the stressor is out of proportion to the severity of the stressor and results in significant impairment in functioning.

The principal interventions for adjustment disorders are psychotherapeutic, educational, and psychosocial. Most crises have a natural time course and resolution. Feelings of distress in response to many of these insults are innate and expected. Psychoeducational interventions are aimed at helping the patient realize that the syndrome is a self-limited and understandable response to the stressor. Often, patients with adjustment disorders have a sleep disturbance, so the short-term use of a soporific (diphenhydramine 25-50 mg, hydroxyzine 25 mg, trazodone 50-100 mg, or mirtazapine 7.5-15.0 mg) or a sedative-hypnotic (zolpidem 5-10 mg, zaleplon 5-10 mg, eszopiclone 2-3 mg, or ramelteon 8 mg) could be considered to assist in reestablishing a normal sleep-wake cycle. In general, benzodiazepine use should be avoided, because at this time there is no evidence that the early use of these agents prevents the eventual development of more serious disorders such as PTSD (Gelpin *et al.* 1996; Guina *et al.* 2015).

Acute Trauma

Patients who have been exposed to a catastrophic stressor or an acute psychological trauma are at risk for developing acute stress disorder or PTSD (Foa *et al.* 1989). The definition of a traumatic event includes direct personal experience of an event that involves actual or threatened death, injury, or threat to one's physical integrity or witnessing such an event or learning about such an event happening to a family member or close associate. Most people who experience such traumas do not go on to develop any psychiatric disorder, but a significant minority, up to 30%, will develop PTSD.

Behavioral indicators of risk of developing PTSD include heightened levels of arousal and coping via disengagement after a traumatic event (Mellman *et al.* 2001). Personalization of the traumatic event, especially thoughts that one might die, is another risk factor. The typical time course for posttraumatic reactions to resolve is on the order of 4 weeks. During this time, it is extremely common for all trauma victims to experience some of the symptoms of PTSD. One of the main early therapeutic goals should be to educate patients about this time course and to encourage them to return to treatment if these symptoms persist past 4 weeks or become particularly debilitating. Referral to trauma-specific psychotherapies (e.g., rape crisis or violent crime survivor groups) can be helpful to victims of these specific insults, as can cognitive processing therapy, CBT, and eye movement desensitization and reprocessing.

The use of benzodiazepines is controversial in the context of acute trauma. Although these medications may be useful in decreasing overall levels of anxiety, current evidence indicates these medications are ineffective for both the treatment and the prevention of PTSD. These medications may impair the benefit of therapy, and overall, the risk seems to outweigh the benefit (Guina *et al.* 2015). If the decision is made to use these medications, long-half-life agents, such as clonazepam and diazepam, minimize the risk of withdrawal or rebound anxiety (Davidson 2004).

Conditions That Require Medical Evaluation

With any acute change in mental status or sudden-onset change in behavior in a previously well individual, medical causes must be considered first, before it is assumed that the symptoms are a manifestation of a previously undiagnosed psychiatric disorder (Frame and Kercher 1991; Hall *et al.* 1978, 1981). This is especially true when the syndrome occurs outside of the usual age-based window of vulnerability. For example, new-onset psychotic symptoms in a patient older than 40 years or mania in a patient older than 50 years should be considered due to a medical condition until proven otherwise.

Panic Disorder

A patient presenting with new-onset dyspnea, tachycardia, diaphoresis, chest pain, and light-headedness should receive a thorough medical evaluation before being assigned a diagnosis of panic disorder. Many different conditions can present with some or all of these symptoms, including unstable angina and myocardial infarction, hypoglycemia, anemia, pulmonary embolism, asthma, obstructive pulmonary disease, gastroesophageal reflux disease, irritable bowel disease, hyperparathyroidism, hyperthyroidism, pheochromocytoma, Huntington's disease, Parkinson's disease, seizure disorder, and autoimmune disorders, such as systemic lupus erythematosus (Roy-Byrne *et al.* 2006). Only after these medical conditions have been ruled out should a diagnosis of panic disorder be entertained. Current FDA-approved medications for panic disorder include clonazepam and alprazolam (benzodiazepines), fluoxetine, sertraline and paroxetine (selective serotonin reuptake inhibitors [SSRIs]), and venlafaxine (a serotonin-norepinephrine reuptake inhibitor). SSRIs tend to be utilized as first-line treatments because of their general tolerability, lack of potential for dependence/misuse, and good safety profile (Katon 2006).

Dissociative Episodes

Amnestic symptoms and acute states of confusion should always be considered secondary to a medical or neurological condition until proven otherwise. Amnestic symptoms are common after head injury, during cerebrovascular accidents and transient ischemic accidents, in postictal states, with brain tumors, in intentional and unintentional intoxications, and in many other medical conditions. Another important diagnostic consideration is delirium resulting from any number of medical or metabolic causes. Establishing the correct diagnosis in this type of patient is facilitated by extended observation, with repeated assessments. This allows for detection of the fluctuating levels of consciousness and awareness common in delirium and of the temporal evolution of the amnestic symptoms due to other causes. Unobtrusive observation of these patients also allows for assessment of purposeful, deliberate, and organized behaviors, which are observed in patients with psychogenic or factitious amnestic conditions but often are not seen in individuals with medical or neurological conditions.

Catatonia

Catatonia is a syndrome characterized by the presence of at least three of the following symptoms: stupor, catalepsy, waxy flexibility, mutism, negativism, posturing, mannerisms, stereotypy, agitation, grimacing, echolalia, and echopraxia (Fink and Taylor 2006; Taylor and Fink 2003). Catatonia can occur in psychiatric and nonpsychiatric conditions and can be diagnosed in roughly 10% of psychiatric patients in acute inpatient services and ED settings (Fink and Taylor 2006). If a patient has not had previous documented episodes of catatonia in conjunction with a known psychiatric disorder, a medical cause should be sought vigorously. Episodes of catatonic behavior can occur in a variety of neurological and medical conditions, including

metabolic encephalopathies, viral encephalitis, cerebrovascular accidents, epileptic episodes, hypercalcemia, and adverse medication (e.g., antipsychotic) or drug (e.g., phencyclidine [PCP]) side effects. These conditions should be ruled out before a psychiatric diagnosis is made. Although no established standard of care exists for the treatment of catatonia, the patient should be initially assessed for hydration status, deep vein thrombosis risk, and pressure ulcers. First-line treatment for catatonia is a benzodiazepine or electroconvulsive therapy (Fink 2001; Rosebush *et al.* 1990).

Mania or Psychosis

New-onset mania or psychosis should always be approached as being potentially caused by a medical condition. The clinical context will guide the urgency of the medical evaluation. New-onset psychotic symptoms in a 40-year-old and new-onset mania in a 50-year-old should prompt an urgent medical evaluation. Such symptoms appearing in an adolescent or a young adult should still be evaluated medically, although not with the same urgency as in the older adult. These symptoms can be caused by brain tumors, cerebrovascular accidents, autoimmune disorders, multiple sclerosis, and hyperthyroidism. Many medications, including exogenously administered steroids and stimulants, as well as illicit drugs, can provoke manic and psychotic symptoms. Therefore, a thorough physical examination and a urine drug screen are essential components of the diagnostic workup.

Functional Neurological Symptom Disorder (Conversion Disorder)

Functional neurological symptom disorder (conversion disorder) is a diagnosis of exclusion. Accordingly, new-onset neurological symptoms, including nonepileptic seizures, nonanatomical movement disorders, paresthesia, paresis, and amnestic syndromes, should be thoroughly evaluated before being attributed to a psychogenic cause. Management of functional neurological symptoms includes a complete medical assessment and reassurance that the symptoms will resolve with time. Long-term management involves both physical rehabilitation and treatment of the underlying psychological conflict or distress. Family therapy can be a useful tool, given that family dynamics are often an essential part of the psychosomatic response to stress (Hurwitz 2004).

Psychiatric Emergencies That Usually Require Pharmacological Intervention

Management of severe behavioral emergencies typically require psychopharmacological intervention prior to definitive diagnosis (Table 67-4). Many psychiatric patients will have episodes of disorganized, disinhibited, agitated, aggressive, or violent behavior. These behavioral states can occur in individuals who are psychotic, manic, or intoxicated as well as in those who have neurological symptoms associated with traumatic brain injury, dementia, or delirium. Patients who are experiencing severe medication side effects also require pharmacological intervention, as do patients with substance use disorders in a withdrawal state.

TABLE 67-4. Psychiatric emergencies that usually require pharmacological intervention

Emergency	Intervention
Agitated, assaultive, aggressive, or violent behavior	
Etiology unknown	Calm, controlled, and adequate staff
	Seclusion or stimulus minimization

Emergency	Intervention
	Physical restraint
Primary psychotic or mood disorder	Medication:
	Lorazepam
	Haloperidol
	Second-generation antipsychotic
	Ketamine
Substance intoxication	Calm, controlled, and adequate staff
	Seclusion, restraint, and stimulus minimization
	Identify intoxicating agent
	Medication:
	Lorazepam
	Haloperidol
	Second-generation antipsychotic
	Ketamine
Delirium	Determine diagnosis
	Treat underlying cause
	Minimize medications
	If needed, IV or IM haloperidol or second-generation antipsychotic
Dementia	Diagnose underlying medical causes (e.g., urinary tract infection)
	Calm, controlled, and adequate staff
	Seclusion or stimulus minimization
	Reassurance and frequent orientation

Emergency	Intervention
	Low-dose antipsychotics
Substance withdrawal states	
Ethanol or sedative-hypnotic withdrawal	Benzodiazepine to stabilize withdrawal symptoms Controlled taper Referral to chemical dependency treatment
Alcohol withdrawal delirium	Supportive measures Medical intensive care unit Benzodiazepine taper
Opioid withdrawal	Symptomatic relief of physical symptoms Clonidine Antiemetics (promethazine or ondansetron) Loperamide Ibuprofen Methocarbamol Hydroxyzine
Medication side effects	
Antipsychotic-induced dystonia	Acute: Diphenhydramine 25-50 mg IV Maintenance: Diphenhydramine 25-100 mg once daily or

Emergency	**Intervention**
	Benztropine 0.5-4 mg once daily or
	Trihexyphenidyl 2-10 mg daily
Antipsychotic-induced akathisia	Discontinue or reduce antipsychotic
	Propranolol 10 mg two to three times a day
	Benzodiazepine
Neuroleptic malignant syndrome	Discontinue antipsychotic
	Immediate stabilization and medical intensive care:
	Cooling
	Hydration
	Anticoagulation if needed
	Dantrolene
	Benzodiazepine
	Electroconvulsive therapy
Anticholinergic delirium	Discontinue anticholinergic agent
	Use supportive measures
Hypertensive crisis	Manage blood pressure and use supportive measures
Serotonin syndrome	Immediate stabilization and medical intensive care
	Discontinue serotonergic agent
	Benzodiazepine
	Supportive measures
Priapism	

Emergency	**Intervention**
	Discontinue medications Urgent urology consult if no resolution
Selective serotonin reuptake inhibitor discontinuation syndrome	Reassurance and restart medications

Assaultive, Aggressive, or Violent Behavior

Assaultive, aggressive, and violent behaviors can have many different etiologies, including psychotic or delusional ideation secondary to a primary psychotic or mood disorder, intoxication, acute states of confusion associated with dementia and delirium, rage attacks in patients with personality disorders, and deliberate, volitional acts by antisocial individuals. The most important chronic risk factor for predicting violent behavior is a history of such behavior. Acute risk factors include over-or undercontrolled behavior. The former refers to an individual with decreased psychomotor activity, tension, anger, and paranoia, whereas the latter refers to a person who is agitated, intrusive, and verbally provocative. Intoxication is an independent acute risk factor that can potentiate violent behaviors in patients with many different diagnoses.

A well-trained staff of an adequate number in an appropriately designed facility is the best strategy for preventing violent episodes. Staff members who are trained to respond in a calm, deliberate, and nonthreatening manner help to establish an atmosphere of order and control. Preventing a violent act from occurring is preferable to responding to a violent act after it has occurred. It is better to have a patient take a medication voluntarily and orally before his or her behavior has escalated than to be required to involuntarily medicate the patient after a crisis has occurred. Research has suggested that clinicians may overutilize intramuscular injections because they are easy to administer (Damsa *et al.* 2006).

There are several pharmacological options in the acute management of the agitated patient. Available oral agents include benzodiazepines and antipsychotics. Lorazepam in 2-mg doses given every 45-60 minutes will sedate most patients by the second dose. Other alternatives are 15-20 mg of olanzapine, 4-6 mg of risperidone, or 5 mg of haloperidol in a single oral dose. If a patient with a known diagnosis of schizophrenia or bipolar disorder is experiencing a psychotic or manic decompensation, a second-generation (atypical) antipsychotic should be used. If the diagnosis is not known or is unclear, then lorazepam is a better choice, especially as acute intoxication with some agents--for example, anticholinergics such as diphenhydramine--may be worsened by the addition of second-generation antipsychotics. Patients should be monitored for an increased risk of respiratory depression and extrapyramidal side effects.

New alternatives to the established pill or tablet formulations of second-generation antipsychotics are available and have demonstrated positive results in comparative studies. Risperidal M-Tab, Zyprexa Zydis, and Abilify Discmelt are rapidly

dissolving forms of their parent agents. Risperidone is also available in an oral concentrate solution. These formulations exhibit benefit over the traditional pill formulation for patients who "cheek" medications (i.e., store the administered pill in their cheek and subsequently dispose of it rather than swallowing it) (Allen *et al.* 2001, 2005). The FDA has approved an inhaled form (marketed under the name Adasuve) of loxapine, a first-generation antipsychotic with second-generation properties (Alexza Pharmaceuticals, Inc. 2016). This route of administration may have a more rapid onset of action than other formulations; however, the overall clinical utility and safety of this agent have yet to be determined.

Involuntary administration of psychotropic medications is permitted in behavioral emergencies, although wide variations exist in the legal definitions and rules regarding the practice of administering involuntary medication. Clinicians should be well informed about the local definitions and regulations regarding involuntary administration of psychotropic medication. Accurate and timely documentation of the need for restraint and involuntary medication administration is essential. Response to the medication and observation for potential medical sequelae such as autonomic instability should also be documented.

Currently, several medications are suitable and commonly used for intravenous or intramuscular administration in behavioral emergencies: the benzodiazepines lorazepam and diazepam; the first-generation antipsychotic haloperidol; and the second-generation antipsychotics olanzapine, ziprasidone, and aripiprazole. Lorazepam is the most useful and should be the mainstay for controlling behavioral emergencies (Battaglia *et al.* 1997; Foster *et al.* 1997; Salzman *et al.* 1991). Lorazepam is rapidly absorbed from intramuscular injections, has a rapid onset of action and a short half-life, and is anxiolytic as well as sedating. Patients who are being combative generally are experiencing high levels of fear or anxiety, so the anxiolytic properties of lorazepam are an additional advantage. Absorption of intramuscular diazepam can be erratic; therefore, this medication is not particularly useful. Haloperidol should be reserved for patients who are clearly psychotic, with the expectation that they will be receiving long-term treatment with an antipsychotic agent.

In a behavioral emergency, a sufficiently large dose should be given with the first injection to ensure rapid onset of sedation and to minimize the need for a second or third injection. Lorazepam should be administered in a 2-mg dose that can be repeated at 45 minutes if the initial dose is insufficient. Very rarely will any additional injections be required after a second 2-mg dose of lorazepam. The initial haloperidol injection should be 2.5-5.0 mg and should not be repeated for at least 2 hours. Enough time must be given for the medication to be absorbed and for maximal sedation to occur. To prevent dystonia, 1 mg of benztropine should be included with intramuscular haloperidol, and haloperidol doses should not exceed 10 mg in 24 hours. Alternatively, 25 mg of diphenhydramine may be added to prevent dystonia while providing additional sedation. The combination of lorazepam and haloperidol in a ratio of 2 mg of lorazepam to 5 mg of haloperidol is often used to provide adequate sedation and anxiolysis while treating the underlying psychosis.

The injectable second-generation antipsychotics should be reserved for patients who will be given an oral second-generation agent after the immediate emergency has resolved. Intramuscular ziprasidone has been studied in patients with schizophrenia who were psychotic and agitated and is currently indicated for the treatment of this condition (Daniel *et al.* 2001; Lesem *et al.* 2001). In these clinical trials, patients received an initial injection of 10 mg, followed by injections of 5-20 mg every 4-6 hours, for a maximum dose of 80 mg in 24 hours. As defined in the package insert for intramuscular ziprasidone (Pfizer, Inc. 2022), the recommended dose is 10 mg or 20mg administered as required, up to a maximum of 40 mg/day. Doses of 10 mg may be given every 2 hours; doses of 20 mg may be given every 4 hours. The maximum recommended intramuscular dose over 24 hours is 40 mg. Intramuscular ziprasidone appears to have a low incidence of extrapyramidal side effects compared with intramuscular haloperidol (Brook *et al.* 2000). Results from one naturalistic study suggest that the use of intramuscular ziprasidone may reduce time in restraints for agitated patients compared with treatment with a first-generation agent (Preval *et al.* 2005).

Injectable olanzapine has been studied for use in agitated patients with schizophrenia, bipolar mania, or dementia (Breier *et al.* 2002; Meehan *et al.* 2001, 2002; Wright *et al.* 2001). In the schizophrenia trials, patients received up to three individual injections of 2.5-10.0 mg in 24 hours, with the higher doses producing more significant and sustained reduction of agitation. In the bipolar trials, patients received up to three injections of 5 or 10 mg of olanzapine in 24 hours, with significant reduction in agitated behaviors. In the dementia trial, agitated patients received up to three olanzapine injections of 2.5 or 5 mg in 24 hours, with significant reduction in agitation. A review of the literature by Tulloch and Zed (2004) concluded that injectable olanzapine was superior to placebo in all study populations and was superior to intramuscular lorazepam in individuals with bipolar disorder. However, this review further concluded that injectable olanzapine did not differ significantly from intramuscular haloperidol or lorazepam in the management of agitation associated with schizophrenia/schizoaffective disorder or dementia. It is relevant to note that olanzapine is FDA approved for the treatment of schizophrenia and bipolar mania, but not for management of agitation associated with dementia.

Injectable aripiprazole is approved for the treatment of agitation in patients with schizophrenia and bipolar mania. Efficacy studies found that injectable aripiprazole at a dose of 9.75 mg was superior to placebo and comparable to injectable olanzapine. Injectable aripiprazole demonstrated tolerability and symptom reduction without oversedation (Tran-Johnson *et al.* 2007).

Other agents utilized in emergent situations include midazolam and ketamine. Midazolam is a rapidly sedating benzodiazepine and can be given intramuscularly at a typical dose of 2.5 to 3 mg. It has a rapid onset but a short duration, and patients will potentially require additional medications. Midazolam is a potent sedating agent and should not be given without airway support being immediately available (Knott *et al.* 2006). Ketamine has demonstrated efficacy in rapid agitation control at a low dose (5 mg/kg) via intramuscular injection. Again, there must be means available to obtain immediate airway control (Barbic *et al.* 2021).

Primary Psychotic or Mood Disorder

Schizophrenia

Atypical (second-generation) antipsychotics represent the current standard of care for the treatment of acute agitation in patients with schizophrenia (American Psychiatric Association 2004). With proven efficacy and improved tolerability in comparison with haloperidol, these agents represent the first-line treatment in the agitated psychotic patient (Aleman and Kahn 2001; Currier and Trenton 2002; Yildiz *et al.* 2003). The optimal intervention in a patient with schizophrenia who is experiencing an acute exacerbation is to rapidly initiate treatment with a second-generation antipsychotic. In this regard, risperidone and olanzapine are the most useful agents, because both can be initiated at a high therapeutic dose (15-20 mg for olanzapine; 4-6 mg for risperidone) and can be given in multiple oral doses (two or three doses) over a period of 24 hours.

In a patient who is too disorganized or combative to take medication orally, intramuscular administration is the only viable route. Currently, the most commonly available injectable antipsychotics are chlorpromazine, haloperidol, ziprasidone, olanzapine, and aripiprazole. In a patient who is psychotic and agitated, coadministration of a benzodiazepine during the first few days of treatment can be particularly effective in controlling behavior while the antipsychotic response develops. Studies suggest that this combination may reduce the total antipsychotic dosage required and potentially result in fewer adverse antipsychotic effects (Salzman *et al.* 1991; Yildiz *et al.* 2003). One caveat to this choice of treatment is the increased risk of sedation and cardiorespiratory depression associated with the combined use of intramuscular olanzapine and intramuscular lorazepam, which led to a black box warning in the prescribing information provided by Eli Lilly, the manufacturer of olanzapine (Lilly USA 2021).

Bipolar Disorder

The goal of managing acutely manic individuals is to rapidly establish a long-term definitive treatment regimen, which means initiating a mood-stabilizing agent such as lithium (10-20 mg/kg) or valproic acid (20-30 mg/kg) as soon as possible. Prior to initiating either of these two agents, a serum pregnancy test should be obtained and documented as negative, since both agents are teratogenic. Both lithium and valproic acid require time to reach a therapeutic blood level and may take up to 14 days to become fully effective. Until steady state is established, behavioral control can be achieved with oral or intramuscular lorazepam on an as-needed basis or with a second-generation antipsychotic such as olanzapine, risperidone, ziprasidone, asenapine, quetiapine or aripiprazole, all of which are FDA approved for the treatment of acute bipolar mania. Olanzapine, risperidone, and quetiapine have the advantage of being sedating, which can be useful in an emergency room setting. A review of the literature indicated that intramuscular olanzapine was superior to lorazepam monotherapy in the treatment of agitated manic patients (Tulloch and Zed 2004). If the long-term plan does not include an antipsychotic, lorazepam or another benzodiazepine should be used for short-term behavioral control. If, however, the plan is to use both a mood stabilizer and an antipsychotic for long-term management, an antipsychotic should be substituted for the benzodiazepine.

Substance Intoxication

Violent and combative behavior by intoxicated patients is a very common occurrence in psychiatric and medical emergency departments. Alcohol, cocaine, PCP, methamphetamines, g-hydroxybutyrate (GHB), and hallucinogens and "designer" drugs (modified cathinones such as bath salts and Flakka) can lead to violent behavior. Recent research in a large urban psychiatric emergency room suggests that use of designer drugs may be a larger problem than was previously appreciated. In this

analysis, standard urine drug screening systems missed a significant number of cases of drug ingestion. Use of a more sensitive enzyme-linked immunosorbent assay (ELISA) and gas chromatography-mass spectrometry (GC-MS) system identified patients who had ingested opiates and amphetamines that were not detected by the standard screening test. This more sensitive detection system also identified a number of patients who had used designer drugs such as cathinone derivatives and tryptamines, which are not detectable with standard screening systems (Reidy *et al.* 2014).

Ethanol intoxication is a very common cause of violent behavior. The appropriate interventions are physical restraint and sedation with a benzodiazepine or haloperidol if the agitation is significant, to allow the patient to become sober. Once a patient's blood alcohol level is below the legal limit for intoxication, a more definitive evaluation can be undertaken, focusing on presence of any underlying psychiatric diagnosis or other treatment needs.

Prolonged cocaine use can lead to development of both mood and psychotic syndromes. Transient paranoid states are very common in cocaine users, as are frank delusions and hallucinations. Agitated paranoid states accompanying cocaine intoxication can lead to significant violent behavior. Interventions include seclusion and restraint, use of intramuscular lorazepam, and use of an antipsychotic if the patient is frankly psychotic. When the patient is no longer intoxicated, the presence of underlying psychopathology can be assessed.

PCP intoxication can be particularly provocative of agitated, combative, and violent behavior. Fortunately (or unfortunately), PCP use tends to occur in localized geographical regions. In areas where PCP use is common, intoxicated individuals are common in emergency facilities. PCP intoxication can present with frank psychotic symptoms, agitation, disorientation, and disorganized behavior. Violent outbursts can be sudden, unprovoked, and unexpected. Patients in the throes of PCP intoxication can be insensitive to pain, and so may be prone to continued agitation even if seriously injured. Adequate numbers of well-trained staff are essential when dealing with patients who have been using PCP. Restraint rooms should be dark and quiet to minimize stimulation. Intramuscular lorazepam should be used to sedate the patient. The half-life of PCP is 20 hours, so these behavioral states can persist for several days before fully resolving.

Methamphetamines (and designer drugs such as bath salts and Flakka, which are amphetamine-like) and GHB can cause agitated, disorganized, and violent behavior. Methamphetamine can have behavioral consequences very similar to those of cocaine. Because of the long half-life of methamphetamine compared with cocaine, this drug can be particularly provocative of frank paranoid and psychotic symptoms. These patients can have psychotic, paranoid, agitated, and violent presentations.

Presenting symptoms of methamphetamine intoxication often include agitation, hallucinations, suicidal ideation, and chest pain (Derlet *et al.* 1989). Distinguishing stimulant intoxication from other clinical conditions can be challenging, given the symptom overlap. Generally, stimulant-induced psychosis tends to be distinguishable from primary psychotic disorders by the absence of a thought disorder and a prominence of visual hallucinations (Harris and Batki 2000). However, given the potential for comorbidity, a positive drug screen does not completely discount the diagnosis of a mood or psychotic disorder. Treatment should focus on maintaining the patient's safety while awaiting the drug's metabolism and dissipation from the patient's system.

Delirium

Patients with delirium can become disorganized, agitated, and combative. Delirium is defined as a state of disturbance in attention, awareness, and cognition, during which the symptoms occur rapidly and fluctuate with time. Delirium is usually due to one or several general medical conditions or to substance intoxication or withdrawal (American Psychiatric Association 2013). Delirium is a medical emergency and carries a very high burden of morbidity and mortality. The definitive treatment of delirium requires diagnosing the underlying cause and taking corrective action. No medications are currently approved for the management of delirium. Interventions aimed at controlling behavior include restraints, environmental modification including frequent reorientation of the patient, and if needed the use of intravenous haloperidol. Behavioral control is essential so that the patient does not further injure him-or herself or interfere with treatment and to protect staff and other patients. The first intravenous dose of haloperidol should be 2.5 mg. If the individual is still agitated after 2 hours, the dose should be increased to 5 mg. This dose can be repeated in another 2 hours if the person continues to be agitated. Haloperidol therapy has been associated with clinically significant QT prolongation. Once the patient is stabilized, a routine antipsychotic regimen should be initiated, dividing the total daily dosage into two or four doses. The antipsychotic can be decreased and discontinued as the delirium clears. Benzodiazepines are contraindicated in cases of delirium.

Dementia

Patients with dementia can become agitated, combative, or psychotic for many different reasons. The most common cause for these symptoms is a delirium superimposed on the dementia. Definitive diagnosis and treatment of the disorder causing the delirium are essential to achieving adequate long-term resolution. Patients with dementia who are not delirious can become agitated as a result of confusion or psychosis inherent in the neurodegenerative pathology. In these cases, the best interventions are nonpharmacological and include environmental modification, behavior modification, and supportive measures. Aggressive behavior in patients with dementia can be treated pharmacologically, in the short term with low-dose antipsychotics and in the long term with low-dose antipsychotics, the anticonvulsants carbamazepine and valproic acid, the b-blocker propranolol, the SSRI antidepressants, or the anxiolytic drug buspirone. As is true in all geriatric prescribing, low doses and slow titration schedules define the appropriate course. Second-generation antipsychotics are not approved for the treatment of dementia-related psychosis, and the prescribing information carries a black box warning regarding an increased risk of death from cerebrovascular events (e.g., sudden cardiac arrest) and infections (e.g., pneumonia) in elderly patients who are treated with these agents (Schneider *et al.* 2005).

Substance Withdrawal States

Alcohol and Sedative-Hypnotics

Alcohol or sedative-hypnotic withdrawal can result in a frank delirium that is life-threatening (Marco and Kelen 1990; Olmedo and Hoffman 2000). The acute signs of early alcohol, sedative-hypnotic, and benzodiazepine withdrawal are similar and can include autonomic instability, tremulousness, diaphoresis, and gastrointestinal disturbances. Autonomic signs of withdrawal can include tachycardia, hypertension, and hyperthermia. Treatment of this withdrawal state is best accomplished with symptom-triggered (based on vital signs and/or Clinical Institute Withdrawal Assessment [CIWA] scores) administration of a long-half-life benzodiazepine. Use of long-half-life agents such as diazepam or chlordiazepoxide prevents peaks and troughs in blood levels. Lorazepam and oxazepam have relatively less hepatic sequelae. During the first 72 hours, vital signs and/or CIWA scores should be obtained at 2-to 4-hour intervals and additional benzodiazepine given if vital signs are still elevated. This approach has been shown to reduce total time and medication exposure in the detoxification phase. It is important to consider concomitant medications, given that b-blockers prescribed for a general medical condition may mask the autonomic signs of withdrawal.

Alcohol withdrawal delirium (delirium tremens) is a life-threatening medical condition (Erwin *et al.* 1998). This syndrome has a very high mortality rate--up to 35% in untreated patients and as high as 5%-15% in optimally treated patients. The delirium usually develops 48-72 hours after discontinuation of alcohol or sedative-hypnotics, peaks around day 4, and can persist for weeks. The symptoms include autonomic instability, fever, disorientation, perceptual disturbances and hallucinations, agitation, and confusion. Patients with delirium tremens should be treated in a medical intensive care unit. These patients typically require physical restraint and vigorous supportive measures. Intravenous haloperidol can be used to control agitation and psychosis. High doses of benzodiazepines have also been used in this situation to manage agitated behavior.

Wernicke-Korsakoff syndrome is another consequence of long-term alcohol use. Wernicke encephalopathy is the symptom complex of ophthalmoplegia, ataxia, and an acute state of confusion. Wernicke-Korsakoff syndrome is diagnosed if persistent learning and memory deficits are also present. Alcoholic individuals should receive three daily 100-mg doses of thiamine via the intramuscular route from the day of presentation, followed by three daily oral doses to prevent development of this syndrome. Patients should receive the first intramuscular dose before oral or intravenous administration of a carbohydrate load in order to prevent rapid thiamine depletion and emergent development of Wernicke-Korsakoff syndrome. Patients should also be given folic acid and magnesium replacement supplementation.

Opiates

Opiate withdrawal can be exceedingly uncomfortable for the patient but, unlike alcohol and sedative-hypnotic withdrawal, is generally not life-threatening. Accordingly, the goal of opiate withdrawal treatment is relief of pain and suffering. Symptoms of opiate withdrawal include dysphoria, anxiety, irritability, craving, mydriasis, piloerection, diaphoresis, nausea, vomiting, diarrhea, rhinorrhea, lacrimation, insomnia, fever, and hypertension. Onset of this syndrome depends on the half-life of the drug used and with heroin is usually 6-8 hours after the last use. The syndrome can last 2-5 days, depending on the individual patient. Clonidine in doses of

0.1-0.3 mg every 3 hours, up to 0.8 mg/day, can be given to suppress signs of opiate withdrawal (Ahmadi-Abhari *et al.* 2001; Akhondzadeh *et al.* 2000; Charney *et al.* 1981; Gossop 1988). A major side effect of this regimen is hypotension, so the regimen must be carried out in a medically supervised setting. Clonidine should be avoided in individuals who are dependent on both opiates and alcohol or a sedative-hypnotic; clonidine may mask the autonomic signs of ethanol withdrawal without preventing the emergence of delirium tremens. Other agents commonly utilized for symptomatic opiate withdrawal include promethazine or ondansetron, loperamide, ibuprofen, methocarbamol, and hydroxyzine.

Psychotropic Medication Side Effects

Antipsychotics

Several adverse events can occur in patients taking antipsychotics. Dystonic reactions are characterized by extreme muscle contraction and rigidity in a patient with stable vital signs and a clear sensorium. These occur most frequently with high-potency first-generation antipsychotics (Moleman *et al.* 1982; Schillevoort *et al.* 2001). Young males are particularly susceptible to dystonic reactions. Most dystonic reactions are extremely uncomfortable and frightening to the patient. Treatment of these reactions is typically 1-2 mg of benztropine via the oral or intramuscular route. An alternative is diphenhydramine in doses of 25-50 mg via the oral or intramuscular route. Dystonias that include the eyes, the so-called oculogyric crises, are particularly frightening, as are dystonias that cause laryngeal spasms, which can compromise the airway. These reactions should be treated with 50 mg of intramuscular diphenhydramine, which provides rapid relief. Maintenance treatment with 1-2 mg of benztropine twice a day or 25-50 mg of diphenhydramine twice a day should be initiated after the acute reaction has resolved (Keepers *et al.* 1983).

Akathisia is a syndrome characterized by internal restlessness, often perceived as the need to be in motion. This leads to increased psychomotor activity, including pacing, rocking, leg tapping and bouncing, and moving frequently between sitting and standing. The patient may complain of feeling anxious or irritable, or of having the sensation that his or her "skin is crawling." Lowering the dosage of the antipsychotic or switching to a second-generation antipsychotic are treatment options. Propranolol in doses of 10 mg two or three times a day is an effective treatment for akathisia.

Neuroleptic malignant syndrome (NMS) is a potentially fatal delirium that develops in some patients in response to antipsychotic agents (Susman 2001). The diagnosis is made on the basis of the triad of symptoms of altered level of consciousness, muscular rigidity (often described as lead-pipe rigidity), and autonomic instability. The autonomic instability includes hyperthermia, tachycardia, labile blood pressure, diaphoresis, incontinence, and occasional dysphagia and bowel obstruction. Associated findings can include elevated creatine phosphokinase (CPK), leukocytosis, and metabolic acidosis. Later complications include rhabdomyolysis and renal failure. The main interventions in NMS are discontinuation of the offending agent and provision of general supportive measures, including cooling, rehydration, intensive nursing care, and anticoagulation. Pharmacological options can include benzodiazepines, bromocriptine (15 mg/day), dantrolene (100-300 mg/day), or amantadine (200 mg/day). ECT also has been used to treat NMS.

The atypical antipsychotic clozapine can cause catastrophic agranulocytosis in up to 1% of patients treated. This usually occurs within 6 weeks to 6 months of initiating therapy with clozapine. A white blood cell count of less than 3,500/mm^3 or a granulocyte count of less than 1,500/mm^3 warrants discontinuation of the medication.

Other signs of impending marrow failure are fever, flulike symptoms, and sore throat. Discontinuation of the clozapine, supportive measures, and treatment of specific infections if identified are the main interventions for agranulocytosis, and in life-threatening cases, growth factors such as filgrastim may be utilized.

Antidepressants

Adverse events associated with tricyclic antidepressants include anticholinergic delirium, cardiac conduction delays, and seizures. Anticholinergic delirium is more common in elderly and impaired individuals and may be potentiated by concomitant anticholinergic medications. Furthermore, the coadministration of an SSRI or other drug known to inhibit the cytochrome P450 2D6 enzyme with a tricyclic antidepressant can cause dramatic increases in tricyclic antidepressant blood levels and resultant delirium. These drugs also can affect cardiac conduction, can lower seizure thresholds, and are lethal in overdose. The principal intervention is to decrease or discontinue the offending agent.

A hypertensive crisis can occur in an individual who is taking monoamine oxidase inhibitors. This usually happens after ingestion of a large dose of tyramine (which can be found in certain food products) or after an interaction with another medication (e.g., meperidine, other antidepressants, sympathomimetic agents). Discontinuation of the monoamine oxidase inhibitor and management of the hypertension are the appropriate treatments.

Serotonin syndrome is a delirium characterized by altered level of consciousness, autonomic instability, and neuromuscular abnormalities including myoclonus, hyperreflexia, nystagmus, akathisia, and muscle rigidity (Martin 1996; Mason *et al.* 2000). Several different drugs, usually administered in combination, can cause this adverse event. Medications reported to provoke serotonin syndrome include SSRIs, tricyclic antidepressants, monoamine oxidase inhibitors, venlafaxine, trazodone, nefazodone, lithium, tryptophan, meperidine, sumatriptan, buspirone, duloxetine, milnacipran, and amphetamines. Discontinuation of the offending agent and general supportive measures are the principal interventions. Unlike in NMS, bromocriptine can worsen the serotonin syndrome. Other drugs useful in treating this condition are benzodiazepines, cyproheptadine, chlorpromazine, methysergide, and propranolol.

Although not a life-threatening emergency, SSRI discontinuation syndrome can be very frightening and distressing to patients. This syndrome develops after abrupt discontinuation of a short-half-life SSRI, with paroxetine and venlafaxine the two most common agents. Symptoms can include dizziness, malaise, nausea, paresthesias, tremor, ataxia, confusion, myoclonus, anxiety, and vivid dreaming. Symptoms usually develop 48 hours after the last dose, peak around day 4-5, and can last as long as 2 weeks. Interventions include reassuring the patient and restarting the medicine, followed by a very gradual taper.

Priapism is a rare but potentially serious adverse event that has been associated with psychotropic medications including trazodone. This physiological condition is usually self-limiting. However, a patient with an erection lasting for more than 4 hours warrants an immediate evaluation and treatment by appropriate medical personnel (Montague *et al.* 2003). Patients should always be warned of this rare but serious potential side effect.

Conclusion

In the modern era, with changes in the mental health care delivery systems and the resultant limitations placed on the utilization of inpatient treatment resources, the emergency psychiatrist will increasingly be called upon to diagnose and initiate definitive treatment of patients with a wide range of psychiatric disorders. Emergency psychiatrists must balance the needs of individual patients with those of the larger community, the health care system, and the third-party payer system, with a focus on delivering care that is both efficacious and cost-effective. This requires a broad knowledge base, incorporating elements of all branches of psychiatry, and consideration of thorough yet expeditious evaluation, diagnosis, and treatment of patients with mental illnesses.

APPENDIX

of Psychiatric Medications

Robert H. Chew, Pharm.D.
Robert B. MacArthur, Pharm.D., M.S.

		Adult		Pedi
Medication	**Approved indications**	**Usual dosage**	**Maximum (mg/day)**	**Usual dosage**
ANTIDEPRESSANTS				
Tricyclic and tetracyclic antidepressants				
Secondary tricyclics				
Desipramine (Norpramin)	MDD	100-200 mg/day (at bedtime or in divided doses)	300	Ages [?] 13 years: 25-100 mg/day (at bedtime or in divided doses)
Nortriptyline (Pamelor)	MDD	75-100 mg/day (once daily or divided tid-qid)	150	Ages 6-12 years: 1-3 mg/kg/day (divided tid-qid
				Ages > 12 years: 30-50 mg/day (once daily

Note. ADHD = attention-deficit/hyperactivity disorder; CYP2D6 = cytochrome P450 2D6 enzyme; EPS = extrapyramidal side effects; GAD = generalized
disorder; OCD = obsessive-compulsive disorder; PMDD = premenstrual dysphoric disorder; PPD = postpartum depression; PTSD = posttraumatic stress d
Mitigation Strategy.

-- = not available; bid = twice daily (or divided into 2 doses); IM = intramuscular; IV = intravenous; PO = oral; prn = as needed; qid = four times daily (or
sublingual; tid = three times daily (or divided into 3 doses).

CD = controlled delivery (extended release); CR = controlled release (extended release); ER = extended release; IR = immediate release; LA = long acting
(extended release); XL, XR = extended release.

		Adult		
Medication	**Approved indications**	**Usual dosage**	**Maximum (mg/day)**	**Usual dosage**
				or divided tid-qid
Protriptyline (Vivactil)	MDD	15-40 mg/day (divided tid-qid)	60	Ages [?] 12 years: 15 mg/day (divided tid)
Tertiary tricyclics				
Amitriptyline (Elavil)	MDD	50-150 mg/day (at bedtime or in divided doses)	300	Ages [?] 12 years: 50-100 mg/day (once daily or in divided doses)
MDD, hospitalized patients	100-200 mg/day (at bedtime or in divided doses)	300		
Clomipramine (Anafranil)	OCD	150-250 mg/day (at bedtime or in divided doses)	250	Ages [?] 10 years: 100-200 mg/day (at bedtime or in divided doses)
Doxepin	Depression and/or anxiety			
	Mild to moderate symptoms	75-150 mg/day (at bedtime or in divided doses)	150	
Severe symptoms	300 mg/day (at bedtime or in divided doses)	300		
Doxepin (Silenor)	Insomnia (sleep maintenance)	3-6 mg at bedtime	6	

Note. ADHD = attention-deficit/hyperactivity disorder; CYP2D6 = cytochrome P450 2D6 enzyme; EPS = extrapyramidal side effects; GAD = generalized
disorder; OCD = obsessive-compulsive disorder; PMDD = premenstrual dysphoric disorder; PPD = postpartum depression; PTSD = posttraumatic stress d
Mitigation Strategy.

-- = not available; bid = twice daily (or divided into 2 doses); IM = intramuscular; IV = intravenous; PO = oral; prn = as needed; qid = four times daily (or
sublingual; tid = three times daily (or divided into 3 doses).

CD = controlled delivery (extended release); CR = controlled release (extended release); ER = extended release; IR = immediate release; LA = long acting
(extended release); XL, XR = extended release.

		Adult		Pedi	
Medication	**Approved indications**	**Usual dosage**	**Maximum (mg/day)**	**Usual dosage**	
Imipramine (Tofranil)	MDD	50-150 mg/day (at bedtime or in divided doses)	200	Ages [?] 13 years: 30-40 mg/day (at bedtime or in divided doses)	1
	MDD, hospitalized patients	250-300 mg/day (in divided doses)	300		
	Nocturnal enuresis			Ages 6-12 years: 10-50 mg at bedtime	5
				Ages > 12 years: 10-75 mg at bedtime	75
Trimipramine (Surmontil)	MDD	50-150 mg/day (at bedtime or in divided doses)	200	Ages [?] 13 years: 50-100 mg/day (at bedtime or in divided doses)	1
	MDD, hospitalized patients	250-300 mg/day (at bedtime or in divided doses)	300		
Tetracyclics					
Amoxapine	MDD	200-300 mg/day (at bedtime or in divided doses)	400		
	MDD, hospitalized patients	200-300 mg/day (at bedtime or	600		

Note. ADHD = attention-deficit/hyperactivity disorder; CYP2D6 = cytochrome P450 2D6 enzyme; EPS = extrapyramidal side effects; GAD = generalized disorder; OCD = obsessive-compulsive disorder; PMDD = premenstrual dysphoric disorder; PPD = postpartum depression; PTSD = posttraumatic stress d Mitigation Strategy.

-- = not available; bid = twice daily (or divided into 2 doses); IM = intramuscular; IV = intravenous; PO = oral; prn = as needed; qid = four times daily (or sublingual; tid = three times daily (or divided into 3 doses).
